ABSTRACT

A longitudinal study was designed in 1986 to investigate why some high-ability minority students follow through with their plans to enroll in college and major in mathematics, science, or engineering (MSE) fields, while others do not. Data came from three sources: (1) 1985 Scholastic Aptitude Test (SAT) files of a sample of minority students planning to major in MSE fields and scoring above 550 on the SAT mathematics test; (2) a detailed survey questionnaire completed in 1987; and (3) a status survey in 1990. This report of Phase 5 describes the results of causal modeling using The LISREL Computer Program to determine the direct and indirect effects of gender, socioeconomic status, high school variables, and college variables on student status 5 years after high school. Most important to persistence in science and engineering were the type of college attended (2-year or 4-year), minority support systems early in college, and commitment to science or engineering by the sophomore year. The roles of other variables are discussed, and the report concludes with practical recommendations for counseling and intervention. Appendix A is a table of variable and outcome correlations. Appendix B is a correlation matrix of measured variables. Appendices C, D, and E contain LISREL computer data for best fitting model and for each gender. (SLD)

Acknowledgements

I am indebted to my colleague, Thomas L. Hilton, who began this project in 1985 and collected the data which I have had the opportunity to analyze. I am also grateful for his very thoughtful review of this report.

In addition, I thank Nancy Robertson for her work on the reorganization and documentation of the database for this special analysis.

My thanks also go to three additional reviewers: Donald Rock, William M. Boyd, and Willie Pearson, who provided valuable comments and suggestions.

Abstract

Concern over the underrepresentation of minorities in mathematics, science, and engineering led to this longitudinal study begun by Thomas Hilton in 1986 under a grant from the National Science Foundation. The purpose of the study was to investigate why some high-ability minority students follow through with their plans to become scientists or engineers, while others with the same plans do not.

Data came from three sources: (1) 1985 SAT files of a sample of minority students planning to major in math, science, and engineering and scoring above 550 on the SAT mathematics test, (2) a detailed survey questionnaire completed in 1987, and (3) a status survey in 1990.

Hilton reported results of the first four phases of the project, including multiple regression analyses. This report of Phase V describes the results of causal modeling using LISREL to determine the direct and indirect effects of gender, SES, high school variables, and college variables on student status five years after high school.

Most important to persistence in science and engineering were the type of college attended (2-year or 4-year), minority support systems early in college, and commitment to science or engineering by the sophomore year. The role of other variables and their effects on commitment and persistence are discussed in technical detail. Important gender differences are also discussed. The report concludes with a list of practical recommendations for counselors and heads of intervention programs both at the high school and college levels.

BACKGROUND TO PHASE V

Concern over the underrepresentation of minorities in mathematics, science, and engineering (MSE) led to this longitudinal study of high-ability minority students under a grant from the National Science Foundation. The purpose of the study was to investigate why some high-ability minority students follow through with their plans to become scientists or engineers, while others with the same plans do not.

This study was begun and directed by Hilton in 1986. Two reports, completed prior to this one, are now available (Hilton, Hsia, Solorzano, & Burton, 1989; Hilton, Hsia, Cheng, & Miller, 1994). Hilton and his colleagues began by sampling high-ability students who took the Scholastic Aptitude Test (SAT) in 1985 and followed the progress of those students for five years. Students had to have scored at least 550 on the SAT mathematics test section (which places them among the top 29% of the SAT population), and they had to have indicated that they planned to major in MSE in college. MSE was defined to include agriculture, architecture, biological sciences, computer sciences, engineering, medical and dental professions, mathematics, and physical sciences. Social sciences and psychology were not included.¹ The initial sample contained all qualifying students from four underrepresented minority groups: 354 American Indian, 2,666 Black, 1,488 Mexican American, and 690 Puerto Rican students. To this group were added random samples of 688 Asian American and 404 White students satisfying the same selection criteria.

Information from the SAT files contained not only test scores, but data from the Student Descriptive Questionnaire (SDQ) completed by most students who register to take the SAT. Included among these data were self reported grades, self ratings of various abilities, family background, and high school activities.

¹The decision regarding which disciplines to include in MSE was made in accordance with the consensus of the NSF Committee on Equal Opportunities in Science and Engineering (CEOSE).

In the spring and summer of 1987, two years after these students graduated from high-school, Hilton and colleagues sent a lengthy questionnaire, entitled the Postsecondary Experience Survey (PES), to all students in the sample and used extensive followup procedures to encourage the return of questionnaires. The PES asked about high school experiences, factors influencing career plans, current educational status, and life values. Fifty-five percent of the total sample returned the PES. The largest response came from White students (71%); the lowest response was from Asian Americans (47%). The parents of all nonrespondents were sent a short postcard questionnaire to learn the status of their students. Postcard responses from parents increased the overall response to 73%, but because the information on the postcard was limited to status in 1987, post-graduation information that might explain student status was available only on those who returned the PES.

Data were then collected at a third point in time--in 1990--five years after high school. An attempt was made to contact by telephone all students who had given permission to do so. The remainder were sent a short questionnaire. The total number of students whose outcome status could be determined from the various combinations of survey responses was 3,840 (64% of the original sample).

As a criterion measure, Hilton constructed a persistence scale ranging from a score of "0" for students who never enrolled in science or engineering and showed no subsequent interest after taking the SAT, to a score of "5" for full persistence, which included those students who were either still enrolled as undergraduates in MSE, or had graduated with an MSE degree and were working in an MSE field, or were enrolled in graduate school in MSE. He then used stepwise multiple regression to predict persistence from five blocks of variables (a total of 32 variables) derived from the SDQ and the PES. He found that 14 of those variables had significant regression weights. The largest standardized weight was 0.30, and that variable was personal commitment to MSE early in college.

Other variables, from the most heavily weighted to the least heavily weighted, were early college GPA ($\beta = 0.16$), SAT mathematics score ($\beta = 0.10$), belief that their high school honors courses were an important influence on their MSE plans ($\beta = 0.10$), early college mathematics grades higher than other grades ($\beta = 0.08$), attending a four-year college versus a two-year college ($\beta = 0.08$), belief that enjoyment of their major was an important influence on their choice to stay in MSE ($\beta = 0.08$), belief that interest in their MSE coursework was an important influence on their choice to stay in MSE ($\beta = 0.07$), participation in MSE activities in college ($\beta = 0.07$), gender ($\beta = -0.06$, with female being a disadvantage), second-choice major field also in MSE ($\beta = 0.06$), plan to have a professional job at age 30 ($\beta = 0.05$), taking advanced mathematics courses in high school ($\beta = 0.05$), number of advanced placement courses taken ($\beta = -0.06$), and finally, as college students, feeling it was important to make contributions to science ($\beta = 0.05$).

When the block of race and ethnicity variables was added last to the multiple regression, it made no additional contribution to the multiple correlation. In other words, when a number of background and experiential variables were held constant, there was no difference in persistence rate attributable to ethnicity.

All in all, the multiple correlation between persistence in MSE and these variables amounted to 0.61. Therefore, only 36% of the variance in the persistence score was explained by all of these variables.

This list of variables gives us some indication of the abilities and experiences related to persistence in MSE. Although multiple regression is the most standard prediction model, it often leaves us with little, if any, understanding of the mechanisms by which these variables affect the outcome, if, in fact, they affect it at all. Because of this limitation and others, we proposed a fifth phase to the project, namely, a comprehensive data analysis with causal modeling.

RATIONALE FOR PHASE V: COMPREHENSIVE DATA ANALYSIS

Although the descriptive analyses and multiple regression of Phase IV provided a good sense of which variables are associated with persistence in MSE, they were inadequate as analytical tools for understanding the process by which the variables affect persistence. Furthermore, multiple regression alone has at least three severe limitations.

First, in a longitudinal study, we measure different variables at different times. Gender affects interests and achievement in high school, which affect interests and performance in college, which affect college outcome. But gender also affects interests and performance in college directly, and all of these affect college outcome, both directly and indirectly. A single regression analysis cannot sort out direct and indirect effects.

Second, the regression weights on the independent variables (prediction variables) depend on two things: (1) the true relationship between the independent and dependent variables, (in this case, between the predictors and persistence), and (2) the reliability of the measurements. When we interpret regression results, we tend to forget about reliability. Gender is a reliable variable. Expressed interest in MSE courses has relatively poor reliability because people interpret the question in different ways and respond differently to rating scales. We refer to a measure having poor reliability as one with a lot of measurement error. Reliability can be improved by asking the same question many different ways and combining the results. That is why a mathematics test has more than one problem. A single question about interests, or about grades, or about the degree to which your father influenced your college plans has relatively low reliability and as a result, will have lower correlations with other variables and will be weighted lower than it should be in a regression equation. That correlation or regression weight is said to be *attenuated* because of measurement error.

Third, ordinary regression analyses deal poorly with variables that are not normally distributed. In survey data, we often have binary variables, such as gender (1=male, 2=female), and we have numerous variables on interval scales (1=strongly disagree, 2=disagree, etc.). The distributions of responses are rarely normal. It is possible, of course, to "normalize" all variables before entering them into a regression analysis, but researchers rarely do this.

With an additional grant from the National Science Foundation, we undertook an entirely new analysis based solely on those minority students who enrolled in college and who completed the PES. The sample was restricted in this way so that nearly complete data would be available on everyone studied. The sample included people who persisted in MSE as well as those who switched majors or dropped out of college.

A structural equation modeling approach developed by Jöreskog and Sörbom (1993), using LISREL, avoids the limitations of multiple regression described above. The approach to the analysis consisted of first laying out a general time line, showing the path of students from one point in time to the next, as shown below.

Even though data were collected at three points in time (marked by dates and bullets), the data actually refer to at least five different times. Pre-high school variables, such as gender and socioeconomic status (SES), come first. They can affect everything thereafter. High school experiences, plans, test scores, and grades come next, and they can affect everything thereafter. Early college activities and experiences come next, and they can affect all information collected in the PES survey, such as values, opinions, and early college grades; they can also affect persistence directly. Finally, grades, values, and opinions as stated in the PES affect outcome in 1990: either students are

in MSE or they are not. In this *recursive* model, variables are in a causal chain, each affected by all earlier variables, and each affecting all later variables. The first limitation of ordinary multiple regression noted above is avoided by this model in which direct and indirect effects can be separated.

The next step was to define the variables to include in the model and to ensure that they were placed correctly on the time line. This step also dealt with the second limitation we noted concerning ordinary multiple regression, namely, the inability to correct for measurement error. By combining several measures of the same variable into one *latent variable*, the LISREL program provides corrections for attenuation by computing an estimation of the reliability of each measure and increasing the regression weight accordingly. It then produces a set of multiple regression equations relating each latent variable to preceding variables at each point in time. Details of the process by which latent variables were defined will be discussed later.

The third problem with ordinary multiple regression, nonnormality of variables, is handled by normalizing the observed variables before they are entered into the regression analysis. A preprocessing program entitled PRELIS (Jöreskog & Sörbom, 1988) screens the input data, normalizes it, and produces product-moment correlation coefficients for continuous variables (such as SAT scores), polychoric correlations between ordinal variables (such as questionnaire responses on 5-point Likert scales), and polyserial correlations between ordinal and continuous variables. The resulting correlation matrix is input to the LISREL program.

PROCEDURE

Sample

Path analysis, like ordinary regression analysis, produces estimates of how well each independent variable predicts an outcome variable. If some students followed a pathway in life along which they missed a large set of experiences that other students had, they could not answer questions about those experiences, and for obvious reasons, we could not expect to compute estimates of how well those experiences (that they never had) affected their persistence in science. Someone who never enrolled in college, for example, could not answer the large body of questions on undergraduate experiences. One could not guess, statistically or otherwise, how those students would have answered questions on undergraduate experiences if they had them. Students who never enrolled in college were therefore excluded from the analysis, not because they were unworthy of study, but because much of the necessary data for prediction was not available for those students, and the data that were available were not comparable to the data for the rest of the sample.

Because this study focused on persistence of minority students, the comparison sample of White students was excluded from all analyses. Students for whom there were no early college data or outcome data were also excluded. Those students who omitted an occasional question, as nearly all students did, were not excluded. The numbers of students for whom essentially all data were available are shown by ethnic group and gender in Table 1.

Table 1. Sample Size by Gender and Ethnic Group			
Ethnic Group	No. Male	No. Female	TOTAL
American Indian	108	38	146
African American	609	505	1,114
Mexican American	495	194	689
Asian American	176	103	279
Puerto Rican	232	97	329
TOTAL	1,620	937	2,557

Fifty-eight percent of the male sample were either working in or studying science or engineering at the time of the final follow-up survey in 1990. Only 48% of the female sample persisted to that status in 1990. However, there was no significant difference among ethnic groups, for either gender, in the percentage who persisted in science and engineering.

Variables

In a path analysis with corrections for attenuation, there are both **measured** and **latent** variables. The distinction between the two types of variables is important.

Measured variables (sometimes called **observed** variables) include test scores, self ratings and self reports, scaled questionnaire responses which include statements of satisfaction, perceived influences of various people and programs, importance of various life activities, and statements about values. All measured variables are fallible in the sense that they may be false, exaggerated, or misunderstood by the person answering the questions. Some students tend to answer questions differently from other students, by marking more extreme responses, for example. Test scores are all subject to random measurement error.

These sources of error result in measures that are less than perfect indicators of the construct they are designed to measure. How well a variable measures what it was designed to measure is one indication of its reliability.

Latent variables are the constructs that the measured variables are designed to measure. SAT mathematics score is a measured variable; "true" mathematical ability is a latent variable. By combining multiple measures of the same ability, we attempt to construct a latent variable. Similarly, by presenting the student with several different statements that reflect the same attitude, an appropriately weighted combination of responses to those statements may be treated as a latent attitudinal variable.

The path analyses conducted in this study first involved the creation of latent variables from measured variables. Equations predicting persistence in science or engineering were then computed from latent variables whenever possible.

The next two sections will describe the measured variables available in the database and the latent variables constructed from them.

Measured Variables. The entire database contains hundreds of high school and college variables. Because of the different pathways students might follow, not all variables are answered by all students. Questions, for example, asking students why they dropped out of school would obviously only be answered by those who dropped out. There is no way to estimate how a persister would have answered a question about why he dropped out. To do so would be to imply a fundamental contradiction. Therefore, to conduct the path analysis, we had to restrict the pool of variables to those answered by all, or nearly all, of the students.

The measured variables included categorical, continuous, censored, and ordinal variables. These distinctions are worth noting.

Categorical variables are ones with no scale, or an arbitrary scale. Examples are gender, ethnic group, whether or not students took an honors course in a particular subject, and whether or not they were "in science or engineering" at a particular point in time. Students were regarded as being in science or engineering if they were enrolled as students (either graduate or undergraduate) and majoring in science or engineering, or if they were employed in science or engineering.

Continuous variables are those with a large number of scaled options, such as SAT verbal scores, which may range from 200 to 800. Scores are distributed between those two extremes, and few people, if any, score at the extremes. Censored variables are continuous variables which have an artificial cutoff. In this database, SAT mathematics score is on a censored scale because only students with scores of 550 or higher were selected for the study.

Ordinal variables are the most common in this database. Their scale is simply an ordering, generally having no absolute zero and with scale interval sizes being unknown. They consist primarily of Likert-type scales, and in the PES survey data, they were designed to measure attitudes, self ratings, perceptions of the degree to which people and programs affected student decisions, degrees of satisfaction with college life, and importance of participating in various activities in the future.

Latent Variables. Each latent variable consisted of several measured variables. Socioeconomic status is a latent variable made up of father's and mother's education and family income. Each latent variable is a construct represented by a factor in the factor-analytic sense. Because it consists of more than one measured variable, its reliability is generally much higher than that of a single measured variable.

Unlike the earlier analysis by Hilton et al (1994), the path analysis used criterion variables defined in terms of the student's status at a particular point in time. Two such variables were defined, one as an indicator of status in 1987, when the student completed the PES, and the other as an indicator of status in 1990, when the final follow-up survey was conducted. Each student was given a

score of "1" if he or she was "in science or engineering" and a score of "0" otherwise². It was most important, because the path analysis dealt with events at several points in time, to define variables so that they were placed at the proper point in time. They could not be defined in such a way as to imply a process over a period of time, otherwise a cause and effect could easily get reversed or placed incorrectly.

Four measured variables--gender, type of college attended (2-year or 4-year/university), self-reported college science grade average, and status in 1990--were treated as latent variables because there was only one measure available for each of these variables.

Preparation of Data

LISREL accepts as input either a correlation matrix or a variance/covariance matrix. Because the survey data consisted of a mixture of ordinal, continuous, dichotomous, and censored variables, the input matrix was prepared using the PRELIS 2 program (Jöreskog & Sörbom, 1988; Jöreskog & Sörbom, 1993b). The input matrix contained, in each cell, the type of correlation appropriate to the scales of the particular pair of variables. For example, the value entered in the matrix for the correlation between SAT verbal score and score on the Test of Standard Written English would be a product-moment correlation coefficient. The value for the correlation between the two dichotomous variables, gender and status in 1990, would be a tetrachoric correlation coefficient. Because it is assumed that each variable has an underlying standard normal distribution, variables are first normalized before correlations are computed. Missing values, because they appear to occur more or less at random, are treated by pairwise deletion.

²Respondents were regarded as "in MSE" if they were employed in a science or engineering field or if they were enrolled in MSE either in undergraduate or graduate school. There were very few whose status was difficult to resolve. If a respondent was still in college majoring in engineering but was employed outside engineering, he or she was still regarded as "in MSE," the assumption being that the employment was temporary and providing an income while the person was completing an engineering education.

Building and Testing Models

The procedure for developing and testing models is anything but an easily explained procedure that follows well-defined steps. It is a hypothetico-deductive process that begins with an expectation of one way in which variables may affect other variables. That expectation is based on theory (educational, psychological, sociological, economic, or causal/logical³). The researcher sets up an expected model and then uses LISREL to test the fit of the model to the data. Very often the expected model fits so poorly that no solution is reached. Some models will fit the data poorly, but the way in which the model fits and misfits can be known by the information the LISREL output provides. In those instances, the model can be adjusted (provided the adjustment makes sense), and the modified model can be tested. When a hypothesized model fits well, LISREL prints a solution, which includes a variety of statistics that will be discussed later. For all of the analyses discussed below, a maximum likelihood (ML) solution was generated, using the input matrix of correlations discussed earlier.⁴

The first models built and tested were designed to establish latent variables. These **measurement models** test whether, and how well, each of a group of selected variables loads on the same factor. That factor represents the latent variable. Standardized factor loadings associated with

³By causal/logical I am referring primarily to chronological and logical sequences. Gender and race may causally affect test scores, but not vice versa. Events occurring in high school can be the cause of college outcomes, but not vice versa. Simultaneous variables, such as race and gender, cannot cause one another. Similarly, even if two observed variables happened to be highly correlated, they would not be set up to load on the same factor unless there were good reason to believe they measured the same construct. That would make no logical sense and would not contribute to our understanding of the process we were studying even if a model having no logical sense happened to fit the data.

⁴It is generally recommended that ordinal variables be analyzed by the weighted least squares method, but to do so requires the asymptotic covariance matrix as well as the matrix of correlations. The asymptotic covariance matrix requires complete data on the part of all subjects. Because of the large number of variables in the models tested, to include only those students who answered all questions would reduce the size of the sample to near zero. Furthermore, Jöreskog & Sörbom (1988) have conducted a number of experiments comparing LISREL analyses of variables having different scale types and have found that despite the fact that ML assumptions were not met, ML still gave good results.

each measured variable are interpreted as standardized validity coefficients. Correlations among factors, because they eliminate the effects of measurement error in the observed variables, are the disattenuated correlations among latent variables. The disattenuated correlations are higher than the zero-order correlations among observed variables.

For example, a latent variable for Minority Support in College is constructed from three variables in the PES. The three variables are measured on ordinal scales, and the individual responses are likely to have only fair reliability. They fit a single factor, however, with quite high standardized factor loadings, the largest being associated with the availability and effect of minority and/or female role models and advisors. The polychoric correlation between this item and status in 1990 was .20. The disattenuated correlation between outcome status and the latent variable for Minority Support, which included this item, was .30.

Following the construction of latent variables, recursive models were developed in which variables at one point in time predicted variables at a later point in time, which in turn, predicted later variables. Both direct and indirect effects of earlier variables on later variables could, therefore, be estimated.

The testing and fitting of these models required many attempts to represent real-world processes with the best possible fit. The reason many models must be tried and modified and tried again is twofold.

First, no measurement model is perfect and unique. Quite often, one questionnaire item measures two or more constructs, and therefore loads on two or more factors, to some degree. The result of placing the measured variable on one or the other factor results in an error variance that reduces the degree of fit of the model, but does not generally affect the interpretation of the model.

Second, some latent variables are highly correlated with each other, but are not identical with each other. Allowing both latent variables to enter a model results in multicollinearity (just as we find

with two highly correlated independent variables in an ordinary regression analysis), resulting in the regression weight on one variable reversing sign. When this occurred, one of the latent variables was removed, and the one explaining the most variance in the dependent variable was allowed to remain. This was a less-than-satisfactory solution to the problem because it did not explain the role played in real life by the discarded latent variable.

Both of these problems occurred frequently, primarily because there were so many variables in the database, and an attempt was made to enter as many as possible into the model so that their roles in a student's development could be best understood. In the results that follow, we will present the best-fitting and most comprehensive path model we were able to develop. This is not the only possible model.

ANALYSIS AND RESULTS

Correlations among Measured Variables

Appendix A lists and defines all of the measured variables that were considered for input to the prediction model. The last variable in the list, MSE90, is either 1 or 0, depending on whether the person is "in MSE" or not in 1990. Variables are arranged in chronological order, with the SAT/SDQ variables appearing first, then the PES variables, then MSE90, which was gathered in the final follow-up survey.

A glance at Appendix A, which also shows the correlation between each item and MSE90 reveals that the correlations of MSE90 with early events (high school and family variables) were low, whereas correlations with many later events (college variables) were quite high. Recall that these later events were still three years before the final status measure in 1990, suggesting that whether a student will be in MSE at or after graduation is fairly predictable by the end of the sophomore year of college.

This pattern showing the outcome to be less correlated with early events than with later events does not imply that early events had little effect on outcome. What the pattern suggests is that early events had little DIRECT effect on outcome. In fact, some early events were highly correlated with college variables, such as the type of college the student entered, and those college variables, in turn, had direct effects on student outcome. The early events, therefore, did have their effects on student outcome, but the effects were INDIRECT. (Appendix B shows the full correlation matrix.) It is the purpose of the path model to separate direct and indirect effects so that the process by which events had their effect can be better understood.

Best-Fitting Solution

A very large number of models were developed and tested, beginning with small models having only a few latent variables. The small models generally fit the data quite well but explained little of the outcome. Most large models, on the other hand, misfit in some way. The best-fitting large model, which accounted for 61% of the variance in outcome, contained twelve latent variables. The complete output from the LISREL run is shown in Appendix C.⁵ Each of four of the latent variables consisted of just one measured variable because there was only a single measure available. These variables were gender, college type, self-reported grade average in early college MSE courses, and outcome.

Table 2 lists the other eight latent variables, each of which was made up of two or more measured variables. The left-most column lists the abbreviation used for each latent variable in the LISREL program; its description is in the second column. The abbreviation for each measured

⁵This model was judged to fit the data well, in spite of its large χ^2 , for several reasons. The standardized root-mean-square residual (RMR) was only 0.065. The goodness-of-fit index (GFI) was 0.89. The pattern of residuals did not contain any large residual. A non-zero error covariance existed between CLUBS and STUDGOVT, indicating that people who responded that they were in student government were also in clubs. An examination of the standardized residuals in the LISREL output shows that it was primarily this type of trivial correlation that contributed to the misfit of the model.

**Table 2. Definition of Each Latent Variable and Standardized Factor Loading (λ)
Associated with Each Measured Variable**

Latent Variable		Measured Variable		λ
Abbrev.	Description	Abbrev.	Description	
Ses	Socioeconomic status	FATHEDUC	Father's education	0.89
		MOTHEDEC	Mother's education	0.74
		INCOME	Family income	0.61
MSciAch	Math & science achievement	PHYSGRD	Latest (high school) grade in physical sciences	0.80
		MATHGRD	Latest (high school) grade in math	0.68

variable in the LISREL program is listed in the next column, followed by its description in the following column. The right-most column lists the standardized factor loading associated with each measured variable.

The intercorrelations among the latent variables are shown in Table 3. These correlations, because they have been corrected for attenuation, are different from the correlations of their component variables shown in Appendix A and B. From this table, we see that the latent variable entitled Commit, which is composed of two statements from the PES expressing the enjoyment of their field of study and willingness to make a commitment to it, is the most highly correlated with Outcome. Understanding how the remaining variables affected that enjoyment and commitment cannot be known from the correlation table alone.

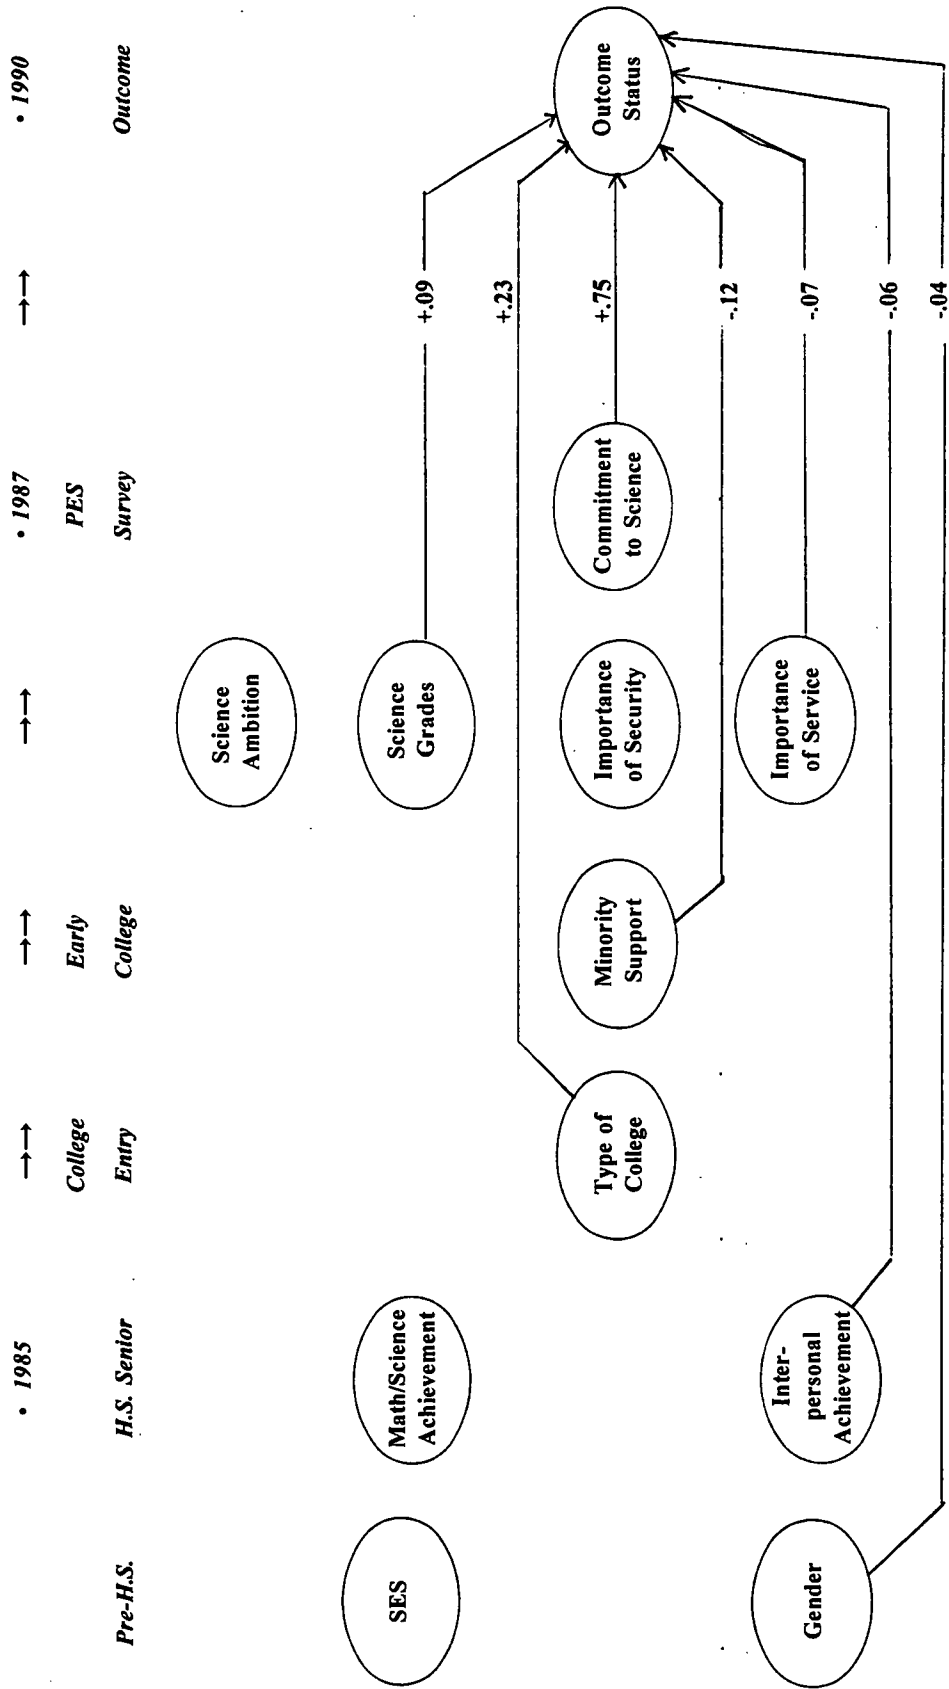

Table 3. Disattenuated Correlations among Latent Variables (N = 2,410)												
Variable	(1)	(2)	(3)	(4)	(5)	(6)	(7)	(8)	(9)	(10)	(11)	(12)

Direct Effects on Outcome in 1990. Figure 1 is a path diagram showing the latent variables arranged along a time line. The causal arrows show the DIRECT effects of each preceding variable on Outcome. Numbers on the arrows are standardized regression weights. The three variables (SES, Math/Science Achievement, and Science Ambition) showing no arrow to Outcome did not, according to the model, have any direct effect on Outcome. One might ask how this is possible, given that Science Ambition, for example, is correlated 0.54 with Outcome (Table 3). According to the model, Science Ambition works indirectly through Commitment to science. The desire to make scientific or technological contributions, according to the model, results in a commitment to science or engineering as a career. It is that commitment that keeps the student on course for three more years.

Although data were collected at only three points in time, questions in the SDQ and PES refer to different points in time, and furthermore, some events, for logical reasons, must have preceded others. For example, it is likely that Minority Support early in college affected Science Ambition, rather than vice versa, even though the questions were answered at the same time. The questions on Minority Support require reflection over the first two years in college, whereas the questions on Science Ambition refer to the person's feelings at the moment he or she answers the questions.

One might wonder, however, why commitment to science should occur after, say, science ambition. The reason is that the model was first tested with all of the latent college variables occurring simultaneous. Science ambition and commitment were so highly correlated that they caused a colinearity problem. There were two possible remedies: either one latent variable or the other had to be removed from the model, or, one had to be placed later than the other. Because there was a good logical reason to do so, commitment was placed later than science ambition. If the model had not made sense by placing one variable later than the other, the latent variable contributing most to explaining the outcome (the one with the larger standardized regression weight) would have been retained.

Figure 1
Best Fitting and Most Comprehensive Model
Showing Direct Effects on Outcome Status

Commitment to MSE in 1987 had the greatest power to predict whether the student was in MSE in 1990. The second most important direct effect was type of college attended. This says that not only did the type of college have indirect effects explained by differences in minority support systems, differences in values acquired in each type of college, and differences in knowledge acquired as reflected in MSE grades, but the type of college had other kinds of effects on persistence. Students attending four-year colleges and universities during their sophomore year were more likely to be in MSE three years later⁶.

The other variables shown in the model had little direct effect on outcome, though their factor loadings were statistically significant. MSE grades early in college had a direct effect on outcome three years later. What is surprising is that the effect was not larger. We must keep in mind here that these are self-reported grades, and students do not always report grades accurately.

Minority support, according to the model, has a small negative direct effect on outcome. This reversal of sign on the regression weight is a colinearity effect that could not be removed without removing the minority-support factor from the model altogether. Because the effects of minority support systems are important in this study, the factor was retained. The negative sign should not be taken seriously because minority support is seen to have very positive indirect effects which will be discussed later.

Interpersonal achievement, which includes leadership, self ratings on interpersonal skills, as well as participation in clubs in high school, has a slight negative effect on outcome. This result is not new; Sax (1994) found that for men, self-rating on popularity was negatively related to persistence in science.

⁶Further analyses could be done to examine in detail the transfer patterns from 2-year to 4-year colleges, and their relationships with persistence. Such an analysis would constitute a separate study and was regarded as beyond the scope of this project.

The importance of being of service also had a small negative impact on persistence. Not surprisingly, the need to be of service was correlated with the interpersonal achievement factor in high school. This finding was consistent with research on college seniors taking the Graduate Record Examinations in preparation for graduate school. Those planning to leave MSE for another graduate field, after earning a bachelor's degree in MSE, were more likely to value making a contribution to society than were the students planning to continue in MSE (Grandy, 1992).

Gender had a very small direct effect on outcome. The path coefficient was only -0.04 (favoring males), but Table 3 showed the correlation between gender and outcome to be -0.17. Most of the correlation of gender with outcome is accounted for by the intermediate variables in the model. These will be discussed individually later.

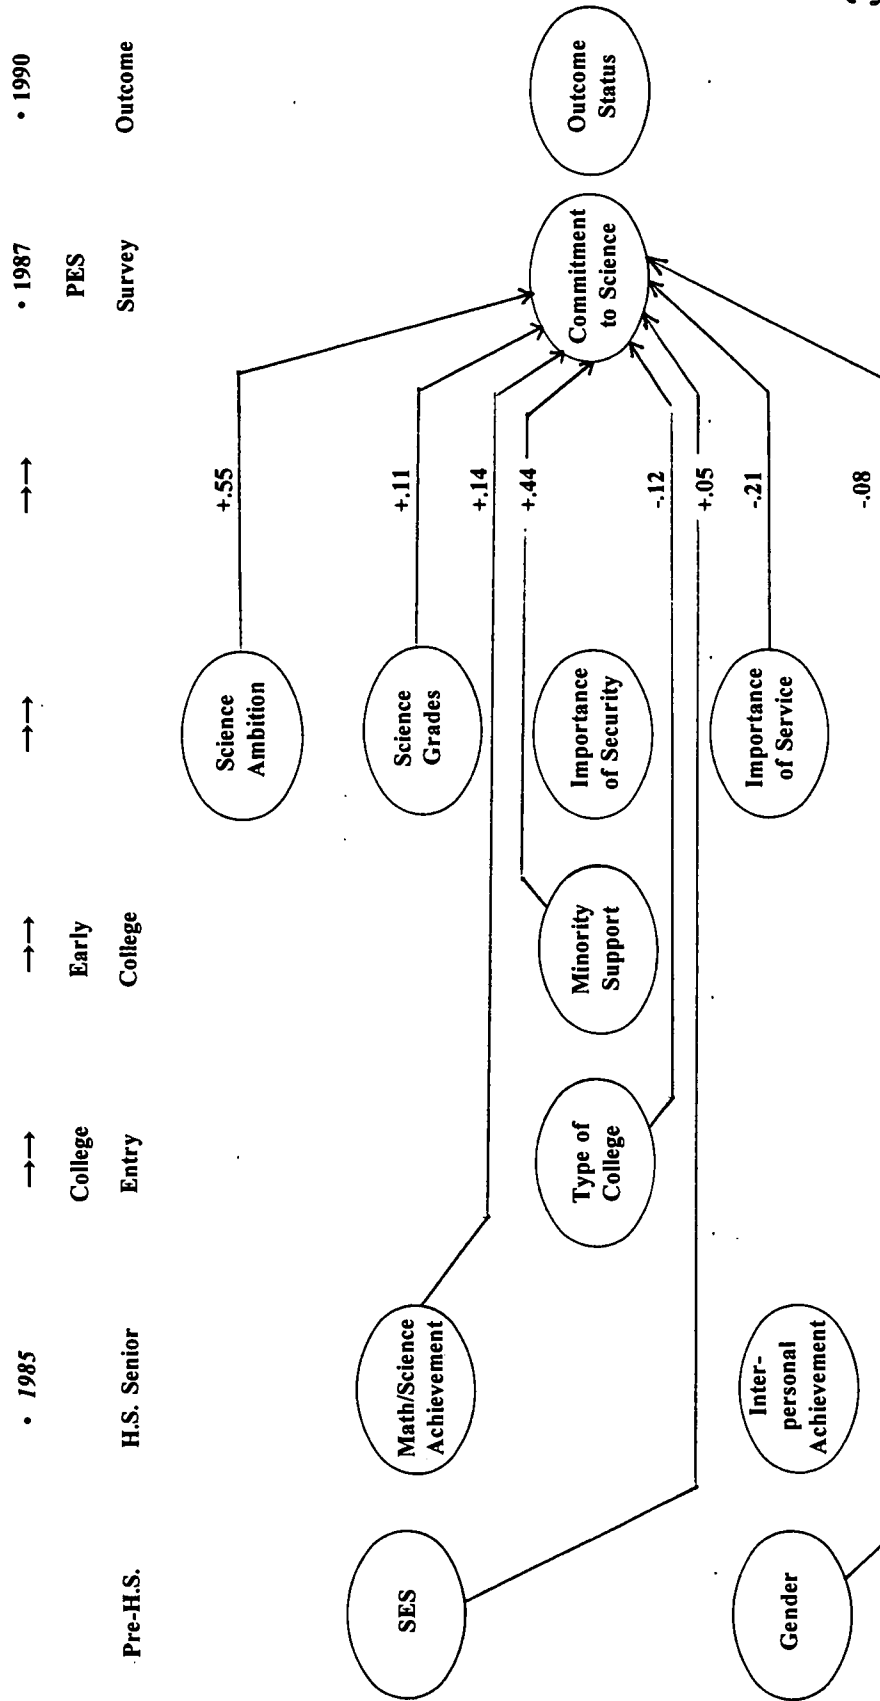

Direct Effects on Commitment to MSE. Because willingness to commit oneself to MSE by the sophomore year of college had such an important bearing on whether the student was still in MSE in 1990, the next part of the analysis worthy of discussion is shown in Figure 2, direct effects on commitment. The largest standardized factor loading, discussed above, was 0.55, which was associated with the Science Ambition factor.

Second most important was Minority Support, with a loading of 0.44. Students who indicated that they had minority role models, advice and support from advanced students of their ethnic group, and a dedicated minority relations staff were more likely to make a commitment to MSE by their sophomore year of college. Having made that commitment, they were more likely to persist through graduation. Minority support worked both directly and indirectly to affect commitment. Indirect effects will be discussed shortly.

Importance of service to society or the community has a small negative effect on commitment to science as it does on outcome in 1990.

Figure 2

Best Fitting and Most Comprehensive Model
Showing Direct Effects on Commitment to Science

Type of college attended is shown as having a negative effect on commitment to science. This negative sign is another case of colinearity; the type of college attended is actually uncorrelated with commitment, but it does work indirectly and positively on commitment through other college variables discussed below.

Math/science achievement in high school shows some small direct effect on commitment to MSE in college. Insofar as high school mathematics and science grades as well as SAT mathematics score reflect ability and preparation in MSE, we would expect those abilities to affect later commitment to MSE. Most of that effect, however, is indirect, through early college experiences and performance in MSE.

College science grades, although moderately correlated with commitment, have a lesser effect on commitment when other variables are taken into account.

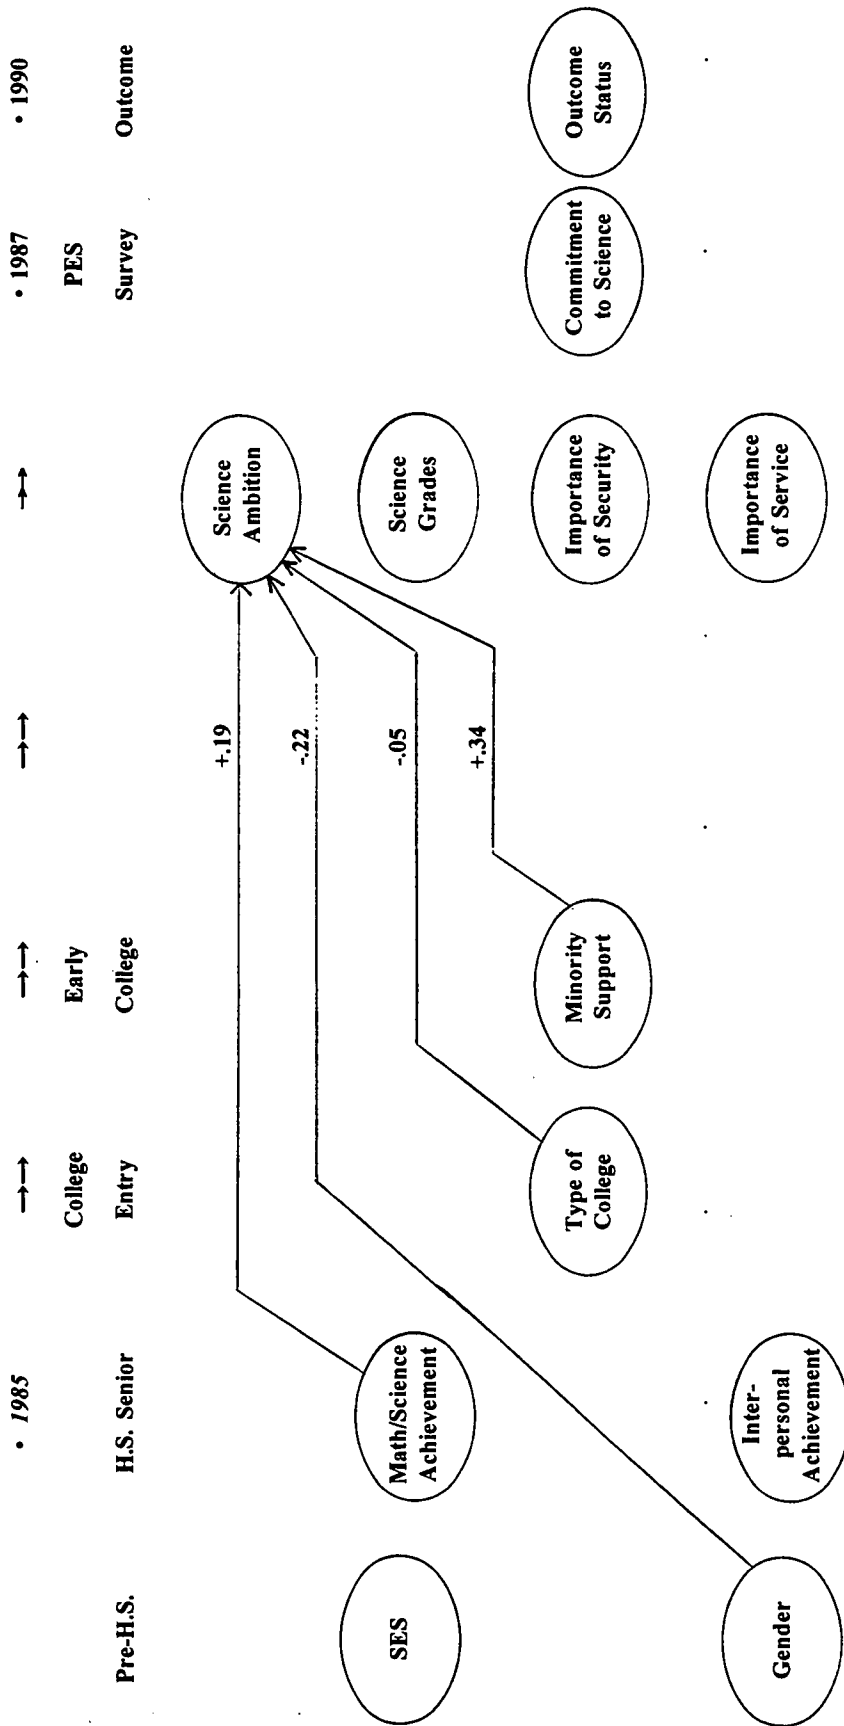

There is a small direct effect of gender on commitment. Aside from ability, performance, minority support, or other variables in the model, males are still more likely to commit themselves to MSE than females are. Whatever other reasons females have for being less likely to commit themselves, those variables are not included in this model.

Direct Effects on Science Ambition. Because science ambition has an important effect on commitment, we will examine the variables that effect science ambition. Figure 3 shows that, in this model, the most important variable affecting science ambition is minority support. Those students who indicated that they had minority role models in college, that they received advice and support from advanced students of their own ethnic group, and had dedicated minority relations staff were more likely to feel that it was important to them to make scientific or technological contributions, to discover new frontiers in science or technology, or to contribute to basic scientific theory.

Gender had a relatively large effect on science ambition. Making the kinds of contributions and discoveries that scientists and engineers make is less important to female than male students, on

Figure 3

Best Fitting and Most Comprehensive Model
Showing Direct Effects on Science Ambition

average. In fact, according to this model, it primarily through this factor of science ambition, rather than grades, for example, that females are less committed to MSE and less likely to persist.

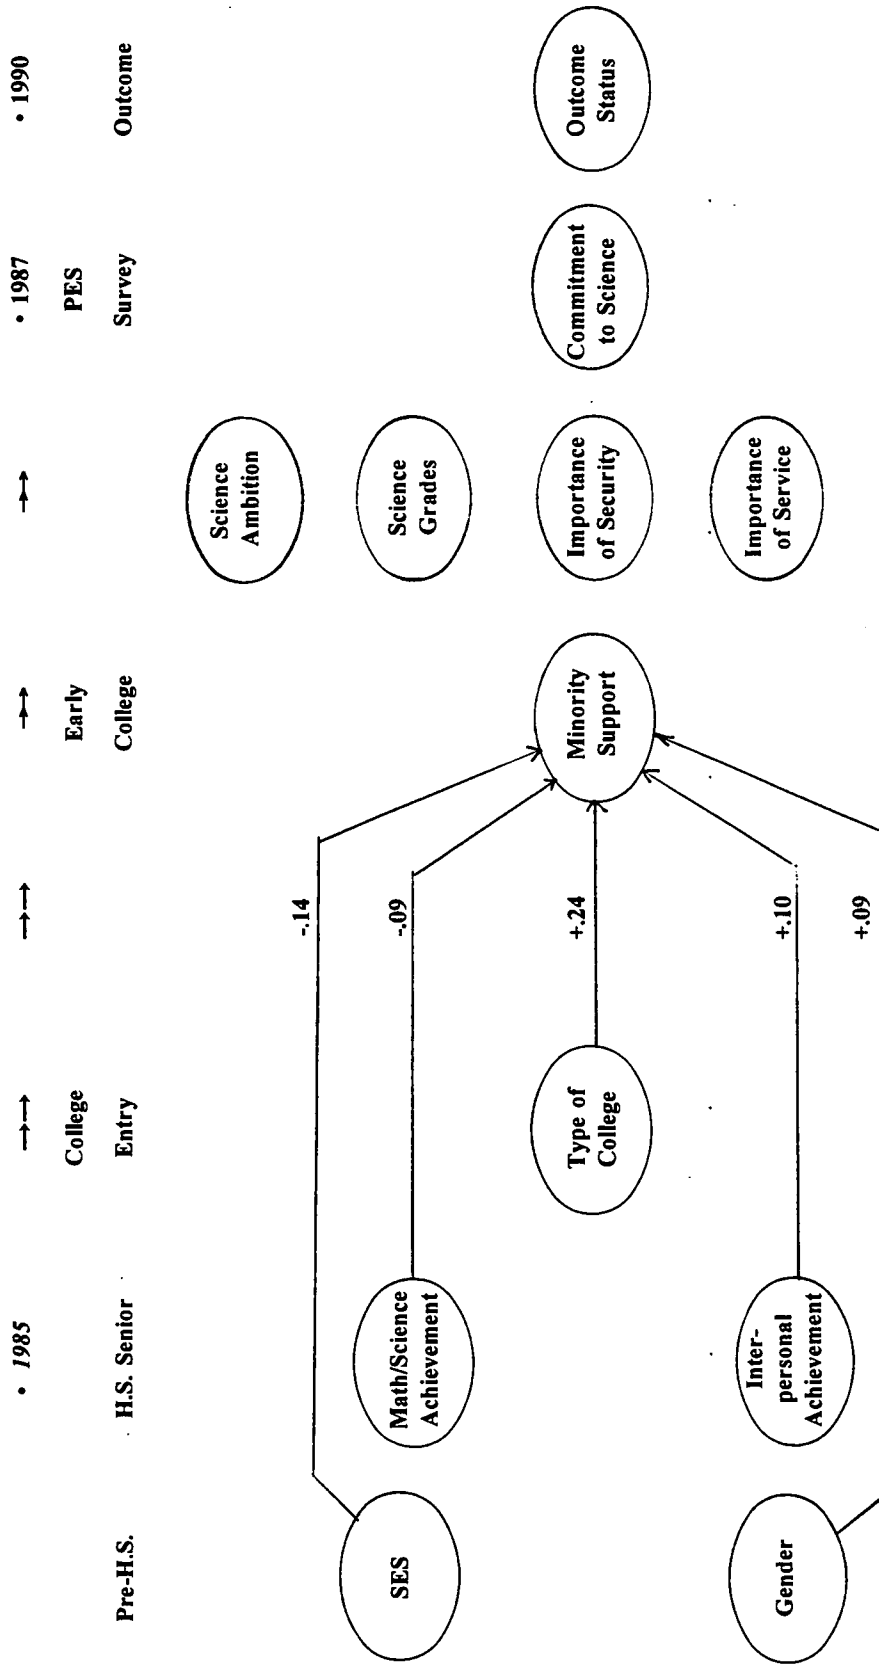

Math/science achievement in high school had a relatively small but direct positive effect on science ambition in college. The type of college attended had very little, if any, direct effect; the negative sign on the factor loading indicating some colinearity. Type of college had a very low correlation with science ambition, but had some positive indirect effect through the availability of minority support systems, discussed next.

Direct Effects on Availability of Minority Support. Minority support, we saw, had positive direct effects on science ambition and commitment to science. Are there any variables in the model able to predict which students were most likely to receive minority support?

Only 8% of the variance in minority support could be explained by the earlier variables in the model. Figure 4 shows that the best predictor was the type of college attended. Students in four-year colleges and universities indicated receiving more minority support than did students in two-year colleges.

Those who had participated in more clubs and organizations in high school and who apparently had greater leadership and interpersonal skills also tended to report receiving more minority support in college than did students who had participated less in social interaction in high school. It is quite possible that there is an underlying social or extraversion variable at play here, and that students who seek out more social contacts in high school also seek out minority support systems in college. This interpretation is consistent with the finding that female students are slightly more likely than male students to indicate that they received minority support in college. Females, more than males, also reported greater interpersonal achievement in high school. So, interpersonal achievement, "female-ness," and minority support in college tend to be associated, but not very strongly.

Figure 4
Best Fitting and Most Comprehensive Model
Showing Direct Effects on Minority Support in College

There is a slight tendency for students of lower socioeconomic status and lower math/science achievement in high school to indicate that they received more minority support in college. It seems likely that these students sought out minority support because their need for support may have been the greatest.

Direct Effects on Type of College Attended. The last diagram, Figure 5, shows that the strongest predictor of type of college attended was math/science achievement in high school, with students earning the highest grades and test scores being more likely to attend a four-year college or university.

To a lesser degree, students from better educated families having higher incomes also were more likely to attend these institutions. To a small extent, the "leaders" and generally more social students were also more likely to attend four-year colleges and universities. Any gender difference in type of college attended was totally accounted for by SES, math/science achievement, and interpersonal achievement.

Discussion of Effects of Each Variable on Persistence

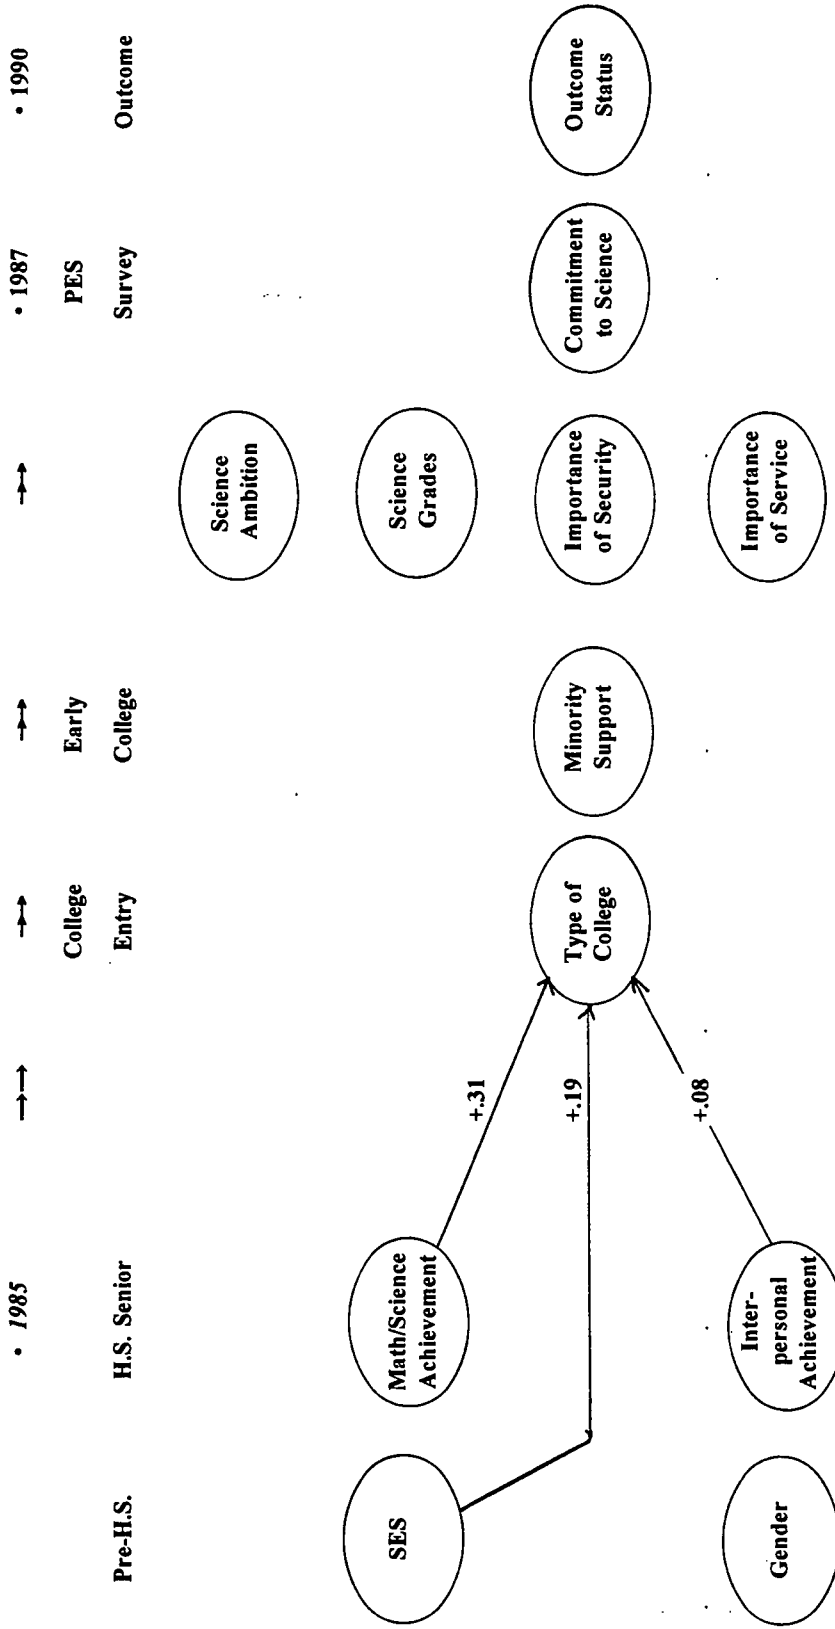

The previous discussion focused on direct effects of all earlier variables on each later variable. A somewhat different understanding is achieved by focusing on the role of each latent variable in the model. This section will discuss the findings in this way.

Gender. The original correlation matrix showed gender to be correlated $-.16$ with whether or not students were still in MSE in 1990. Just what events, between high school and a point in time five years after graduation, might account for the greater loss of females than males from the MSE pipeline?

We see from the model that math/science achievement in high school is NOT a factor. To the contrary, although females earn lower SAT mathematics scores, their self-reported grades in all courses, including physical sciences, are higher than the grades of males. Gender is uncorrelated with

Figure 5

Best Fitting and Most Comprehensive Model
Showing Direct Effects on Type of College Attended

self-reported grades in MSE in college. Therefore, it is not grades that keep females from persisting in MSE.

Interpersonal achievement and activities in high school may, to some small degree, distract MSE students from their goal. Because female students participate more in these social and leadership experiences than do males, the greater social emphasis in their lives appears to have a slightly negative effect on persistence.

Females, slightly more than males, attend four-year colleges and universities. Students attending four-year colleges and universities are more likely to persist in MSE. Therefore, the type of college attended should actually enhance the female student's chances of persisting.

According to the model, the primary college variables that explain the lower persistence rate of female students are science ambition and willingness to make a commitment to MSE. Whatever reasons female students may have for leaving MSE, they are apparently not intellectual reasons but reasons based on what they want to do with their lives.

Socioeconomic Status. The family backgrounds of minority students in this study cover a broad range. Some have parents with no high school degree, and approximately one-fourth have a parent with a graduate or professional degree. This sample of students cannot, as a whole, be regarded as economically or educationally disadvantaged.

It is perhaps surprising that SES did not play a greater role in student persistence. Although students from lower SES families did tend to have lower test scores in high school and were less likely to attend a four-year college or university, their college experiences appeared to compensate for these early disadvantages. The zero-order correlation between MSE90 and father's education was only 0.01. Thus there was no relationship between father's education and whether or not a student was still in MSE in 1990. There was only a very small relationship ($r = 0.05$) between MSE90 and mother's education, and no relationship with family income. Of all the variables in the model, minority support

in college appears to have had the greatest influence in overcoming the early disadvantages of a lower SES background.

Math/Science Achievement in High School. This factor correlated 0.21 with student outcome in 1990. Recalling that the sample consisted of minority students scoring 550 or higher on SAT mathematics, we would expect the correlation to be much higher for the full population of SAT takers. Among high-scoring students, however, this factor still has an important effect on persistence insofar as it affects the type of college attended and the ability to earn high grades in college MSE courses.

Interpersonal Achievement in High School. This variable, which consists of leadership activities, self ratings of leadership and interpersonal skills, and participation in various organizations in high school, has some small but notable effects on students' pathways through college. These activities in high school have a small positive effect on getting into a four-year college or university and on finding minority support in college. They are moderately related to the need to find a career that performs a service to society or to the community. But they tend not to contribute to persistence in science. Rather, they work to a small extent either as a distraction from MSE or perhaps they represent a set of social values that are not satisfied by a commitment to MSE. Although the negative relationship of interpersonal achievements to persistence in MSE is not a strong one, it has also been noted elsewhere (Sax, 1994).

Type of College Attended. Students who were attending a four-year college or university during their sophomore year were more likely to persist in MSE than those who were attending a two-year college at that time. The model also showed that students in four-year colleges and universities indicated greater minority support. Part of the minority support factor was the statement that advice and support from advanced students of their own ethnic group were available. We may assume that students in two-year colleges were less able to envision their futures beyond the sophomore year

because there were no older students, especially minority students, who could offer advice and support and with whom they could identify. Perhaps, in addition, the need to transfer to another institution to complete their studies may serve as an obstacle to their completion. We might expect it to be easier for students to finish what they are already doing than to apply to other institutions during their sophomore year and have to make the necessary move.

Minority Support. According to the model, this factor appeared to have a very important effect on science ambition and commitment to science during the sophomore year, which, in turn, had the greatest effect on status in 1990. Students in four-year colleges and universities appeared to receive the greatest minority support, probably because of the availability of older students and role models of the same ethnic group who could advise and direct them. Minority support had little effect on grades; its primary effect was on the affective domain: science ambition, attitudes, enjoyment, and willingness to make a career commitment.

Grades in MSE. Grades in MSE had less of an effect on outcome than interest and commitment did. It is possible that students were not quite accurate or honest about their grades. If we had had transcript data, we might have found grades to be a better predictor. Furthermore, because these students were of high ability to begin with, higher or lower levels of ability within this range may not have had a great bearing on student outcome.

It may also be the case that motivation is truly more important than grades. Variables in the PES are not specific enough to sort out all of the attitudinal variables. They are all highly intercorrelated but do not load on a single factor. Problems of multicollinearity prevented the addition of other variables, such as satisfaction with instructors or access to computers, into the model.

Science Ambition. The desire to make significant contributions to science or technology, according to the model, was the greatest driving force in making a commitment to MSE. For this sample, minority support in college appeared to kindle and maintain that desire.

The Need for Security. One of the apparent effects, or at least one of the correlates, of minority support was recognition of the importance of being able to find steady work, job security, and success. This need was not related to persistence in MSE, however, but was retained in the model to show its association with minority support.

The Need to Be of Service. A career in MSE is probably not often seen as performing a service. The desire to be of service is moderately correlated with minority support, and according to the model, it is positively affected by the minority support system. The desire to be of service has a small negative effect, however, on persistence in MSE. This pattern of influences suggests that for some MSE students, minority role models and advisors affect students by making them more aware of their ability to serve society and to effect social change, especially if these students were active in student government and organizational leadership in high school. At some point early in college, or later, they switch majors from MSE to a field in which they believe they are more likely to make a contribution. These results are consistent with other research cited earlier.

Commitment to MSE. What is perhaps most remarkable is that the commitment to MSE in sophomore year of college is such a good predictor of MSE status three years later. These two questionnaire items, involving commitment to MSE as a career and enjoyment of MSE as a major field, account for over half of the variance in MSE status three years later.

One thing this model has attempted to do is to explain how minority students in their sophomore year of college were able to arrive at a point at which they could make a career commitment. The model has shown that commitment could also be predicted by a number of background variables, and that 67% of the variance in the commitment variable could be explained by science ambitions, minority support systems, grades, and other background variables.

A Remaining Question

One curious result of the analysis was that the model provided no explanation for the lower persistence rate of females. Results of interviews conducted by the author (unpublished) suggest that some female college science students experience a conflict between their passion for science and their desire to have a family, believing that a science career is too demanding and will not allow them sufficient time with family. There were a set of questions in the PES that pertained to what might be termed "family values." They included importance of finding the right person to marry and having a happy family life, having children, and being able to give children better opportunities than they have had. An attempt was made to include this latent variable in the model, but the LISREL program was unable to compute a solution.

One hypothesis to explain why a solution could not be reached is that family values works differently for men and women. The interview results suggest that it may be a positive incentive for choosing an MSE career for males and a negative incentive for females. To test this hypothesis further, and to see if other variables in the model worked differently for males and females, we tested the model separately for each gender.

Comparison of Separate Models for Males and Females

The question as to whether the same model holds for both males and females is one that can be answered by testing the model for both groups. Methods of testing the equality of factor structures and the psychometric properties of variables for two different samples have been developed by Werts, Rock, Linn & Jöreskog (1976 and 1977). For our purposes here, such a rigorous test should not be necessary. One might expect the factors affecting persistence in science to be somewhat different, or at least differently weighted, for males and females. Furthermore, we might expect some factors, such as family values, to affect each gender in a different way. What follows shows how surprisingly similar the models are for both genders.

We first attempted to put the latent variable for family values in the model and run it just for the male sample. Again, the LISREL program found no solution, so we left it out of the male model. The solution to the final model for males can be found in Appendix D.

For the female sample, the latent variable entitled "security," which included the importance of finding steady work and having job security, did not fit into the model. No solution was reached, so we removed security and inserted the latent variable for family values. This model fit quite well. Appendix E shows the LISREL solution.

For the male sample (N = 1,510), the path model was nearly identical with the model fitted on the total sample. The fit was about the same (RMR = 0.07, GFI = 0.88), and the variance explained by the model was 63% (compared with 61% for the combined sample).

For the female sample (N = 900), the model fit quite well with the inclusion of family values (RMR = 0.07, GFI = 0.87) and explained 63% of the variance. Contrary to the hypothesis based on interview data, family values played a small but positive role in persistence, being correlated 0.12 with commitment to MSE early in college and 0.05 with outcome in 1990.

Other than the two latent variables--security and family values--being different for the two groups, the models were nearly the same. Some minor ways in which the measurement models differed for the two groups are worthy of mention. The factor loading on Math/Science Achievement associated with SAT mathematics score was higher for males than for females (0.44 versus 0.28). Importance of being an inspiring teacher or role model loaded more heavily on the need-to-be-of-service variable for males than for females (0.66 versus 0.55). For females, mother's education and family income played a slightly greater role in the definition of SES for males than they do for females. These differences are rather hard to interpret and may not lend any meaningful interpretation to differences in the models.

Table 4 shows the correlations among the latent variables for each gender. The outcome was correlated somewhat more highly with high school math/science achievement for males than it was for females (0.17 versus 0.25). Social achievements in high school, found to have a slight negative correlation with outcome for males, is not at all correlated with outcome for females (-0.10 versus 0.00).

A greater difference in the correlation matrices comparing males and females is the disattenuated correlation between college type and outcome. For males, that correlation is 0.25, indicating that males who attend four-year colleges and universities are more likely to persist in science than those who attend two-year colleges. For females, this correlation is trivial (0.04); there is essentially no relationship between college type and persistence.

Minority support in college also appears to be more important to persistence for females than for males. However, the question loading most heavily on the minority-support factor is "Minority or female role models and advisors." This factor, therefore, includes female support as well as minority support for the female minority sample. In the model for females, therefore, this latent variable should be renamed "female and minority support" and given a somewhat different interpretation.

Examination of the correlations among latent variables is useful but does not separate the direct and indirect effects of the variables on student status in 1990. To do this we must examine the path coefficients. All of the path coefficients are shown for each gender in Appendixes D and E. Those worthy of note and are as follows:

For males, there is a small negative relationship between math/science achievement in high school and whether they availed themselves of minority support systems in college. For the female sample, there is no relationship. This difference may be due to the fact that for females, minority support systems include female support systems.

Table 4
Disattenuated Correlations among Latent Variables

(10) Commitment	-0.00	0.21	0.03	0.00	0.55	0.75	0.20	0.12	-0.01	1.00	
(11) Outcome	0.02	0.17	-0.00	0.04	0.39	0.55	0.27	0.05	-0.05	0.77	1.00

Science ambition, which we found to be related to gender in some unexplained way, is affected by math/science achievement in high school more for males than for females. This finding may suggest that males, more than females, are likely to commit themselves to a career based on their talents and achievements. Females may recognize that they have math/science skills and abilities, but may not feel that those skills and abilities could or should turn into a career. Another interpretation is that the statements themselves may sound overly ambitious, even arrogant, to some people. If females more than males see making a contribution to basic scientific theory as something that is beyond the dreams of most scientists, they may indicate that such an outstanding achievement is not what they expect to accomplish themselves. They may still, however, plan to be good scientists. These speculations, of course, require more research.

For the female sample, family values are affected by very little in the model. The importance of a family does appear to affect commitment to MSE very slightly, and in the positive direction (contrary to the hypothesis based on interview data).

Commitment to MSE is affected by college MSE grades more for males than for females. This finding is consistent with the finding discussed above showing, for females, less of a relationship between high school math/science achievement and the desire to do science.

Finally, in the prediction of student status in 1990 (outcome), the type of college attended has less effect on outcome for males than for females (path coefficient is 0.32 for males and only 0.09 for females). Commitment to MSE during the sophomore year, especially for females, is almost a guarantee that they will still be in MSE three years later (path coefficient for females is 0.85).

Most of the differences in the models for males and females are quite small. They are pointed out here because, for the variables mentioned, the factor loadings for males and females differ by two or more standard errors. In some ways, however, the path to success does appear to be slightly different for men and women.

Males who are able to enter four-year colleges and universities appear to have greater access to, and need for, minority support systems, especially more advanced students who serve as role models and advisors. Those support systems appear to encourage interest in MSE and promote greater science ambitions. Those with higher ambitions are more likely to make a commitment to MSE as a career. Males making a commitment in their sophomore year are likely to remain in MSE for at least the next three years.

For females, it appears to be less important whether they enter a two-year or four-year college. But for both genders, enjoying MSE and making a commitment to an MSE career by the end of the sophomore year almost ensures that the students of both genders will still be in MSE three years later.

POLICY IMPLICATIONS

An enthusiasm for science and engineering either builds or diminishes during the first two years of college. The availability of a minority support system appears to be an important part of the process of building this enthusiasm, especially for males. Males in two-year colleges are less likely to persist in MSE than are males in four-year colleges. The model indicates that this occurs for at least two reasons, one being that students with weaker academic skills are more likely to attend two-year colleges, and the other being that students in two-year colleges lack contact with more advanced students of their ethnic group who can serve as role models and advisors.

There may be many ways that two-year colleges can strengthen their minority support systems. It appears from the data that for males, it is important to have the advice and support of advanced students of the same ethnic group as well as a dedicated minority relations staff. Perhaps a linkage with a nearby four-year college or university in which minority students could develop personal ties with more advanced students would be productive.

Another advantage of a linkage with a larger institution would be to strengthen students' visions of their educational and professional goals. It can be difficult to envision a personal goal, such as being a scientist or engineer, without first envisioning what it is to be a junior or senior. Perhaps each step of the educational process--not just the goal--should be clearly visible to the student. Those stepping stones to success, namely the junior and senior years, as well as graduate school years, should be in sight for every student. To know the goal without the path, and to see no other minorities on the path ahead, could be discouraging.

A relatively small negative effect on persistence appears to be participation in various types of clubs and organizations. This explains, at least in part, why a smaller proportion of women than men persist -- greater proportions of women than men participate in social activities. One might suspect that there are several factors that may account for this effect. MSE fields are academically demanding, and a student has only so much time to devote to studies and extracurricular activities. Although we do not want to perpetuate the stereotype of the lone scientist, awkward and unsocialized, it is important to impress upon minority students that a commitment to studies will pay off in a satisfying career. Social events not only occupy time that could be devoted to MSE studies, but they can serve as distractions from a goal. The balance between being "well rounded" and developing an area of expertise can be difficult to achieve. Perhaps MSE students could be made more aware of the fact that maintaining this balance throughout life is necessary and not easy.

Related to interests in clubs and organizations is student concern about performing a service to society or the community. Not all students have a desire to serve or have social or political ambitions. But it is unfortunate that for some people the desire to perform a service is in conflict with being a scientist or engineer. Other research, mentioned earlier, confirms that many students leave MSE so that they can do something to benefit society. It is a sad commentary on science and engineering that they cannot be perceived as capable of benefitting society. Science and engineering need the efforts of

the academic community to change their image--a negative image having been largely constructed by the media. Science and engineering departments could take responsibility for improving the image of their professions by pointing out the improvements in medicine, transportation, and creature comforts that have arisen from technology and from our understanding of nature, rather than allowing the media to emphasize the destructive forces of bombs and air pollution. Students do not have to leave MSE to perform a service.

Finally, this model did not emphasize sufficiently the importance of math/science skills because the sample was drawn from students who scored relatively highly on the SAT mathematics test. We would expect the model to show that math/science achievement in high school has very large effects on persistence if the entire population of test takers were studied. Even in this select sample, high-school math/science achievement and college grades had an impact on persistence. While we focus on the various environmental and motivational factors influencing student persistence, it is important not to forget that academic preparation and high quality college course work are essential for minority student success in science and engineering.

RESEARCH IMPLICATIONS

In sorting through the maze of variables affecting minority MSE students, several mysteries have arisen. Valuable insights may be gained by researching these questions:

- What is it about minority support systems that motivate students to enjoy science and engineering and to make a career commitment to an MSE field?

By examining the components of minority support systems in different colleges and universities, we could determine which components make the greatest contribution to minority persistence in MSE. Correlations among variables in the model suggest that minority support actually

increases the student's enjoyment of MSE coursework as well as their decision to make a career commitment. Minority support does not appear to have a direct effect on grades, which suggests that it is not a tutorial component that is operating. Rather, its effects are on the affective quality of MSE studies, perhaps increasing confidence or stressing the importance of study or commitment, or simply the enjoyment of making scientific discoveries. Just what these components are could be learned through more in-depth studies.

- Why does commitment to MSE during the sophomore year almost ensure success through graduation?

Research into the nature of the relationship between sophomore commitment and later persistence could lead us to understand whether it is the act of making a commitment that keeps the student on target, or whether there is something about completing the first two years of coursework successfully that gives the student encouragement to complete the last two years. It may be the nature of the curriculum that contributes to this commitment, with many of the most difficult courses, such as organic chemistry, being taught in the sophomore year. Once over the big hurdle, so to speak, students may feel confident that they can complete the rest. Whatever the reasons, the dynamics of this commitment and later persistence could be better understood, and that understanding may provide important information for curriculum developers.

- Why are minority role models and advisors more important for males than females?

The model indicates that male MSE students appear to need minority support more than female MSE students do. This finding should be confirmed with other data in other contexts to see if it is universally true and to see if the model is being interpreted correctly. If so, the exact dynamics of the relationships between students and minority role models and advisors should be researched.

Perhaps the minority support system works differently for women and perhaps it should be structured differently so as to increase minority female participation in MSE.

- Are attitudes and enjoyment really more important than achievement?

Which is more important to success--attitude or achievement? This is an age-old question, but in the context of minority and female success in MSE, it is an important question. The data in this model seem to suggest that enjoyment of science is far more important for persistence than grades. This conclusion probably applies to high-ability students and not to a general population of high school seniors planning to be scientists or engineers. Recall that the sample was selected from the population of SAT takers earning mathematics scores of 550 or higher. The assumption underlying the sample selection was that anyone scoring over 550 has the academic ability to succeed in science or engineering provided they have the motivation and educational support. The purpose of the study was primarily to explore the effectiveness of various educational and social support systems. No doubt, if the same survey had been conducted on all high school students planning to study MSE, grades and test scores would have played a far greater role in predicting persistence.

This type of analytical model should be tested on different types of student populations to determine how much of our energy and resources should be put into improving cognitive skills and performance in coursework and how much should be directed towards motivational components of minority support programs.

- Why should the type of college attended (two-year or four-year) affect the persistence of males and not females?

It is understandable that two-year colleges lack the minority support offered by more advanced MSE students and that they accept students with more questionable academic records, but it is not clear at all what other effects it has on student persistence. We have no basis for understanding why the persistence rate of females is unaffected by whether they are in two-year or four-year colleges.

First, this finding should be tested on other samples to see if it is true in general. Then, second, if it is true in general, a study should be done in greater depth to see whether there are truly institutional effects or whether some other set of variables (covariates) are operating.

- Why do females have less science ambition than males, even when they have the same levels of achievement?

Findings from this study indicate that even when males and females have the same levels of math/science achievement, females have less ambition to make scientific discoveries and contributions than males do. Do female MSE students have lower aspirations than males? Do they receive less encouragement from professors than males do? Are females less likely than males to associate academic success in a field with choosing a career in that field? Do females entering MSE professions see themselves perhaps as working in a laboratory but not personally making a scientific discovery or contribution? A more detailed study comparing the attitudes and expectations of male and female MSE students may reveal very different views of what it means to be a scientist or engineer, and some commonly held perception on the part of female students may prevent some from achieving all they are capable of achieving.

- Can coursework be more enjoyable?

It has not always been the goal of educators to make coursework enjoyable. Findings from this study indicate, however, that minority MSE students who enjoy their studies are likely to make an MSE career commitment and successfully complete their studies. To increase the numbers of minority students who persist in MSE, it follows that a reasonable approach would be to improve their enjoyment of their courses. The data suggest that minority support systems, in some way, are successfully helping students to do just that. Further research should be conducted to learn what components of the minority support systems are actually increasing enjoyment of coursework. These

components, if identified and understood, could perhaps be implemented in other MSE departments to increase minority participation and success.

RECOMMENDATIONS

Like most research, this study raises many questions that can be pursued with further research, and its findings point in a number of directions that policy makers can explore. Unlike some research, many of the results have implications that can be acted upon immediately by heads of intervention programs and their sponsors, high school and college counselors, and students themselves. The following practical recommendations arise directly from this study. They consist of actions that can be taken by secondary schools and higher-education institutions with very little change to their current practices.

High School Level

- Urge students who have science and engineering aspirations to participate in science clubs and organizations.
- Encourage science and engineering students to apply to four-year colleges and universities.
- Stress the importance of earning high grades in mathematics and science so that they will be admitted to four-year colleges and universities.
- Point out to students, especially males and those from low SES backgrounds, that others like themselves have succeeded in science and engineering; provide role models when possible.
- Provide information to students illustrating ways in which science and engineering serve society; take care not to emphasize problems created by technology over and above the benefits provided by technology.

- Inform students that the first two years of science and engineering coursework in college may be the most difficult, and that if they can complete their sophomore year successfully, they are likely to be able to complete their bachelor's degree.
- Alert students that some courses may be extremely difficult and discouraging, but that most subsequent courses will be less demanding and more enjoyable.
- Encourage minority students, especially males and students from lower SES backgrounds, to attend colleges where minority support systems and role models are available.
- Inform math/science teachers that their encouragement of high-ability minority students has a long-term effect on student persistence in MSE.
- Introduce minority students to minority scientists, engineers, physicians, and other professional/technical role models.

College Level

- Encourage minority students, especially males and those from lower SES backgrounds, to avail themselves of minority support services.
- Provide opportunities for incoming freshmen to establish relationships with advanced students of their ethnic group and to meet with minority advisors.
- Emphasize that freshman and sophomore courses may be very difficult and that students who succeed in science and engineering are committed to hard work and earning high grades.
- Encourage participation in math/science courses that strengthen basic skills.
- Stress the variety of careers in math, science, and engineering so that students who may lose interest in one area can shift to another MSE area in which they can utilize their scientific abilities.

- Emphasize the social and humanitarian benefits of science and technology, especially to students who plan to switch majors because the sciences do not appear to meet the need to serve society.
- Provide linkages between two-year and four-year institutions so that students in two-year colleges can envision their course of study beyond the sophomore year and form relationships with more advanced students.
