ABSTRACT

        This study compares the Questionnaire on Teacher Interaction
(QTI) constructed by Wubbels, et al., for six countries including The
Netherlands, United States, Australia, Slovakia, Singapore, and Brunei. The
Model for Interpersonal Teacher Behavior (MITB) as a "circumplex" model with
specific properties is discussed and an overview of methods to analyze these
properties is given. Earlier research on the validity and reliability of the
QTI is discussed in terms of these methods. Finally, outcomes of analyses of
the validity and reliability of the QTI using data from the six countries is
presented. (KHR)

Students' perceptions of secondary science teachers' interpersonal style in six countries: A study on the cross national validity of the Questionnaire on Teacher Interaction.

1. Introduction

Research has shown that one of the most important problems many experienced and beginning teachers face is maintaining order in the classroom (Veenman, 1992). Order, a critical component of classroom atmosphere, is heavily influenced by the interpersonal skills of a teacher[1] (Créton, Wubbels, & Hooymayers, 1989). With this in mind, Wubbels, Créton and Hooymayers (1985) developed their *Model for Interpersonal Teacher Behavior (MITB)*, to map interpersonal teacher behavior extrapolated from the work of Leary (1957).
Figure 1. *The Model for Interpersonal Teacher Behavior (MITB).*

This model (see Figure 1) maps interpersonal teacher behavior with the aid of two dimensions: an *influence* dimension (describing who is in control in the teacher-student relationship, the teacher or the student) and a *proximity* dimension (describing the degree of cooperation between teacher and students). The influence dimension is characterized by teacher dominance (D) on one end of the spectrum, and teacher submission (S) on the other end. Similarly, the proximity dimension is characterized by teacher cooperation (C) on one end, and by teacher opposition (O) on the other. The two dimensions can be depicted in a two-dimensional plane, that can be further subdivided into eight categories or sectors of behavior: leadership (DC), helpful/friendly behavior (CD), understanding behavior (CS), giving responsibility/freedom (SC), uncertain behavior (SO), dissatisfied behavior (OS), admonishing behavior (OD) and strictness (DO). Each sector can be described in terms of the

[1] The study of teaching is one of the areas of interest of the domain of learning environments research (Fraser, 1998). Apart from an interpersonal viewpoint on teaching, one can take many other viewpoints to analyze teacher behavior, such as a learning activities perspective, a subject-content perspective, a moral perspective or an organisational perspective (e.g. Brekelmans, Sleegers & Fraser, 2000; den Brok, 2001).

2

two dimensions: leadership, for example, contains a high degree of influence and some degree of cooperation; helpful/friendly behavior some degree of dominance and a high degree of cooperation; etc. There is evidence suggesting that the dimensions of the Leary model – hence: the Model for Interpersonal Teacher Behavior – are cross-culturally generalizable (Lonner, 1980). Moreover, the interpersonal dimensions are conceptually related to intercultural dimensions (den Brok, Levy, Rodriguez, & Wubbels, 2002) such as immediacy (Gorham & Zakahi, 1990), approach-avoidance (Andersen, 1985; Hecht, Andersen, & Ribeau, 1989), individualism-collectivism (Kim, Sharkey, & Singelis, 1994) and power distance (Hofstede, 1991).

Based on the Model for Interpersonal Teacher Behavior, Wubbels et al. (1985) constructed the *Questionnaire on Teacher Interaction* (QTI). The QTI originally consisted of 77 items, answered on a Likert-type 5-point scale. The items of the QTI refer to the eight sectors of behavior – leadership, helpful/friendly, understanding, giving responsibility/freedom, uncertain, dissatisfied, admonishing and strict – that jointly make up the MITB. Since its development, the QTI has been the focus of well over 120 (learning environment) studies in many countries (den Brok, Brekelmans, Levy, & Wubbels, 2002) and has been translated into more than 15 languages (Wubbels, Brekelmans, Levy, van Tartwijk, & Admiraal, 1997). The original QTI, designed for secondary education, also formed the basis for a number of other versions for primary education, higher education, principals and supervisors (den Brok, 2001).

In the present study, QTI data are compared for 6 countries: the Netherlands, USA, Australia, Slovakia, Singapore, and Brunei. The construction process of the QTI differed between these six countries. The QTI was first constructed in the Netherlands between 1978 and 1984 (Wubbels, et al., 1985). Its development involved four rounds of testing - using different sets of items -, interviews with teachers, students and teacher educators, and researchers judging the face validity of items. In this manner, out of a pool of over 200 items, 77 items were selected for the final version. The American version was created between 1985 and 1987 by translating the set of 77 items from the Dutch version, adding several items (since several items could be translated in more than one way), and adjusting this set of items based on three rounds of testing (Wubbels & Levy, 1991). Ultimately, the American version contained 64 items. The American 64 items-version of the QTI was initially also used in Australia (Wubbels & Levy, 1993), but ultimately Australian researchers ended up with a more economical 48-item selection (Fisher, Henderson, & Fraser, 1995). The Slovak version consisted of a translation of the American QTI, with other items added that better represented the Slovakian context. Ultimately, this resulted in a version with 64 items that was different from the American version (Gavora, Marek, & den Brok, in press). The Australian 48-item version, in turn, formed the starting point for the Singapore and Brunei versions, both consisting of the same number of items. The Singapore secondary education version consisted of the exact same set of 48 items in English (Fisher, Chiew, Wong, & Rickards, 1996). The Brunei version was developed by translating the 48 items of

the Australian version into Malay and involving several people in checking the back-translation into English (Scott & Fisher, 2000).

As can be seen from the process above, researchers employed several activities to ensure the quality of the QTI in their respective countries. First of all, they went through an elaborate and painstaking process of translation and back translation, in some cases interviews with teachers and students, several rounds of testing and observations in the classroom (Fraser, 2002). Second, researchers have assessed the degree to which the eight scales (or sectors) of the QTI in their countries were reliable (Cronbach's alpha) at the student and teacher/class level and were able to detect differences between classes and teachers (den Brok, 2001). Third, many researchers computed (inter)correlations between the eight scales in order to see if these roughly represented a circular ordering (e.g. den Brok, 2001; Evans, 1998; Henderson, 1995; Rawnsley, 1997; Rickards, 1998; Scott, 2001). In some cases, researchers established stability (Multilevel Lambda) (Snijders & Bosker, 1999) of the scales across classes (den Brok, 2001). In other instances, researchers computed dimension scores and correlated these (Levy, den Brok & Wubbels, 2001), to see if they were independent. A small number of studies conducted *exploratory* factor analyses (Soerjaningbsih, Fraser, & Aldridge, 2002; Wubbels & Levy, 1993) or *confirmatory* factor analyses (den Brok, 2001; den Brok, Levy, Wubbels & Rodriguez, in press; Wubbels & Levy, 1991) in order to see if two, independent dimensions underpinned the eight scales of their QTI. In some cases, statistical analyses were performed on (aggregated) class level data, but in most cases on (individual) student level data.

Using the above methods, results have been reported on the quality and validity of the QTI for the Netherlands (den Brok, 2001; Wubbels & Levy, 1993), the USA (Wubbels & Levy, 1991; 1993), Australia (Fisher, Fraser, & Wubbels, 1993; Fisher, Henderson, & Fraser, 1995; Henderson, Fisher, & Fraser, 2000), the United Kingdom (Harkin, Davis, & Turner, 1999), Canada (Lapointe, Pilote, & Legault, 1999), Singapore (Fisher, Rickards, Goh, & Wong, 1997; Goh & Fraser, 1996), Brunei (Scott & Fisher, 2000), the Philippines (Oberholster, 2001), Israel (Kremer-Hayon & Wubbels, 1992), Hong Kong (Yuen, 1999), Korea (Kim, Fisher, & Fraser, 2000), Fiji (Coll, Taylor, Fisher, & Ali, 2000) and Indonesia (Soerjaningsih, et al., 2002). Only two studies are known to the authors that investigated cross-cultural validity of the QTI (e.g. Fisher, et al., 2000; Wubbels & Levy, 1991). These studies reported small differences between countries in correlational patterns, outcomes of factor analyses, reliability and percentages of variance at the class level. One other study, on multicultural classes in the USA, investigated intercultural validity of the QTI (den Brok, et al., in press). This study showed that for four cultural groups – African-Americans, Asian-Americans, Hispanic-Americans and Caucasian-Americans – the scales of the QTI were ordered in a circular structure. However, the scales displayed relatively large dispositions from their theoretical positions in two of the four cultural groups (the African-American and Hispanic-American groups). Thus, for these two groups the MITB received less support than for the other two cultural groups.

While the field has gained much experience from the application of the QTI in different contexts (Fraser, 2002) and much is known about the quality of the QTI within various countries, there is need for a more elaborate cross-cultural investigation (see also Fraser, 1998; Wubbels & Brekelmans, 1998). From a more methodological stance, earlier cross-cultural investigations were limited in terms of the countries involved (only two per study), while most of the studies investigating validity and reliability within separate countries used limited analysis techniques (discussed in a later section).

Apart from the arguments above, research is in need of cross-culturally valid instruments, since they provide opportunity to compare practices between countries, also in the light of large-scale international educational (effectiveness) studies. Cross-culturally valid instruments may provide opportunity for assessment, self-evaluation and staff-development of teachers in international schools or multicultural education contexts. Finally, such instruments open up opportunities for researchers and other interested educators to work on joint research projects and use similar language, models and terminology.

This paper compares student perception data from six countries and uses specific analysis methods to analyze the validity and reliability of the QTI. In this way, it adds to the existing knowledge base and compensates for some of the limitations of earlier studies. The paper starts with a discussion on the MITB as a circumplex model with specific properties. Next, an overview of methods to analyse these properties is given. Then, earlier research on validity and reliability of the QTI is discussed in terms of these methods. Finally, the paper presents outcomes of analyses regarding the validity and reliability of the QTI using data from six countries.

2. The circumplex Model for Interpersonal Teacher Behavior (MITB)

As stated before, the MITB describes interpersonal teacher behavior in terms of two dimensions (influence and proximity), that underlie eight behavioral sectors, ordered in a two-dimensional plane. The MITB is a special model because of its statistical properties and is theoretically linked to a particular branch of models called *circumplex models*. Circumplex models are based on a specific set of assumptions (Blackburn & Renwick, 1996; Fabrigar, Visser, & Browne, 1997; Gaines, Panter, Lyde, Steers, Rusbult, Cox, & Wexler, 1997; Gurtman & Pincus, 2000). These are:

- Assumption 1: the eight behavioral sectors (or scales) of the model are represented by two, uncorrelated dimensions (or factors).
- Assumption 2: the two interpersonal dimensions that lay behind the sectors are uncorrelated[2].
- Assumption 3: with the two interpersonal dimensions, the sectors (or scales) of the model can be ordered in a circular structure.

[2] Most variants of the circumplex assume two underlying dimensions. Since the MITB originates from Leary's (1957) model, it is additionally assumed that these two dimensions are uncorrelated or independent. However, this second assumption is not necessarily specified for other variants of the circumplex (Fabrigar, et al., 1997).

- Assumption 4: the sectors (or scales) of the model are equally distributed over this circular structure.
- Assumption 5: the sectors (or scales) occupy specific positions on the circle (as given in Figure 1), which can be determined with a goniometric circle function.
- Assumption 6: the sectors (or scales) of the model share similar amounts of variance (e.g. have equal communality).

To test these assumptions behind the circumplex, psychologists have developed a number of statistical tests and procedures.

Assumption 1 and 2 are very general and usually tested by applying (exploratory) factor analyses or multidimensional scaling methods to the sector scores of individuals. With these methods, it can be checked if two or more factors underly sector scores. In these analyses, the optimal number of factors or dimensions is determined by looking at the amount of variance explained and/or eigenvalues of the factors extracted. If factors explain less than 10 percent of 'additional' variance, or eigenvalues are below one, or eigenvalues hardly drop between factors (this can be seen by looking at the scree-plot), the number of factors is optimal. Depending on the extraction and rotation methods used, it can also be determined if these factors are independent (assumption 2)[3]. Of course, the overall amount of variance explained by the factors should be as high as possible. Assumptions 1 and 2 can also be tested by means of confirmatory factor analyses (using software such as LISREL, EQS, AMOS, Mplus, Circum, etc.). The model specified in such analyses contains two factors or dimensions, but allows for free estimation of factor loadings and correlation between the two dimensions. To test the second assumption, the correlation between the two factors can be set to zero. If model-fit indicators are sufficiently high, it seems very likely that two (independent) factors structure the perception scores on the sectors. The factor loadings found can be used to establish empirical locations of the sectors in the model. If only the first and second assumption are tested and confirmed, psychologists speak of a *spatial representation model* (Gurtman & Pincus, 2000), *irregular circumplex* or *non-circumplex model* (Gaines, et al., 1997).

Assumption 3 is more specific and incorporates assumptions 1 and 2 (e.g. starts from the premise that sector scores are represented by two, uncorrelated dimensions). If the eight sectors are ordered in a circular structure, this should be represented by their (inter)correlations. This means that correlations between pairs of scales or sectors are greater for sectors closer on the (interpersonal) circle, and smaller if they are more distant. Thus, correlations between opposing scales are smallest (most negative), while correlations between neighbouring scales are highest (positive), and correlations decrease in (equal) steps if one moves from neighbouring scales towards opposing scales

[3] Principal component methods result in independent factors or dimensions. However, researchers are advised to use maximum likelihood methods and rotation by hand, instead of principal component methods and varimax rotation – which are default methods in most statistical packages – because these better account for circumplex properties (den Brok, 2001).

(Gurtman & Pincus, 2000; Tracey, 1994; Tracey & Schneider, 1995). Tracey (1994) developed a statistical tool called RANDALL[4], to analyse if a correlation matrix has a circular structure. This program compares correlations pair-wise and checks if the correlation pattern described above can be found in the data. For instruments with eight scales (or sectors), such as the QTI, 288 comparisons between scales can be formulated and tested. The outcome of this software is a Correspondence Index (or CI), that basically represents the proportion of correlations that is in accordance with the expected circular ordering, and a *p-value*, that indicates how significant the index is. A CI-value of .5, for example, means that as many comparisons are in accordance with a circular ordering as comparisons that are not, while a value of .75 means that twice as many comparisons are in accordance, as comparisons that are not. Of course, for a circular structure, CI should be close to 1 and its p-value should be significant. Browne (1992) developed another tool to test the circular structuring of sector scores. He developed a software program that can test different circumplex models behind a correlation matrix: CIRCUM[5]. The most relaxed variant that can be tested only assumes a circular ordering[6]. By looking at the model fit indicators it can be determined if the model applies to the data. The Browne method is more stringent than the method of Tracey, since it also implies that sectors have equal distances to the circle center (Blackburn & Renwick, 1996). If the sector scores can be structered in terms of a circle, psychologists speak of a *circular order model* (Gurtman & Pincus, 2000).

Compared to assumptions 1, 2 and 3, assumptions 4, 5 and 6 are even more specific, and usually involve less exploratory and descriptive methods of testing (Fabrigar, et al., 1997; Gaines, et al., 1997; Gurtman & Pincus, 2000). Of these last three assumptions, assumption 4 postulates the most relaxed circumplex structure. In this variant of the circumplex, it is assumed that sectors have equal distances between them on the circle, however, their exact positions on the circle are not specified. The CIRCUM software (Browne, 1992) can be used to test this model. If model fit indicators are sufficient, it seems likely that the scales have equal distances on the circle. This variant of the circumplex is called the *equally-spaced circumplex* (Gurtman & Pincus, 2000).

In assumption 5, not only is it assumed that scales have equal distances on the circle, but their position on the circle is also fixed and can be determined exactly with the goniometric circle function (Gurtman & Pincus, 2000). The factor loadings in this model represent the positions displayed in Figure 1. The factor loadings for the influence dimension are .92 (DC and DO), .38 (CD and OD), -.38 (CS and OS), and -.92 (SC and SO). For the proximity dimension, factor loadings are .38 (DC and SC), .92 (CD and CS), -.92 (OS and OD), and -.38 (SO and DO). This model can be tested with LISREL (Jöreskog & Sörböm, 1989) or Mplus (Muthén & Muthén, 1999) by specifying a two-dimensional factor model with zero correlation between the factors and the exact (thus fixed) factor

---

[5] This software can be downloaded without costs from: http://quantrm2.psy.ohio-state.edu/Browne/.
[6] This model is also called the *unequally spaced, non-equal communalities model*.

loadings specified above. By looking at model fit indicators it can be determined if the model fits the data. This version of the circumplex is called the *ideal circumplex* (Gaines, et al., 1997).

Finally, assumption 6 takes the premise that sector scores have been measured in a similar manner and share variance (communality). This assumption is special in nature, since it applies to the operationalisation of the model: variance that is unique for each sector is regarded as measurement error (Fabrigar, et al., 1997). The assumption can be tested within LISREL or Mplus by restricting the estimates of measurement error to be equal across sectors or in CIRCUM by specifying a model with equal communalities. The specifications can be added to any of the models testing for assumptions 1 to 5. However, since questionnaires or other instruments almost never succeed in measuring sectors with the same amount of communality or error, this sixth assumption is usually not tested[7].

Apart from the methods above, researchers have also developed a number of indices that allow researchers to investigate the degree to which their *empirical* (circumplex) model, resulting from the testing of assumptions 1 to 5, deviates from the *(theoretical) ideal* circumplex. First, one can determine the empirical angular location of a sector, using the factor loadings that resulted from (confirmatory or exploratory) factor analyses, and compare these to the ideal locations, resulting in *angular dislocations*[8] (Pincus, Gurtman, & Ruiz, 1998; Wagner, Kiesler, & Schmidt, 1995). Second, one can compute the distance of a sector to the circle centre[9] - also called *vector length* - and determine the degree of variation in these (Blackburn & Renwick, 1996; Pincus & Gurtman, 1995). In the ideal case, variation in vector length is minimal. Third, one can compute ideal and empirical influence and proximity scores for each respondent and determine the correlation between both sets (Blackburn & Renwick, 1996; Wiggins, Philips, & Trapnell, 1989)[10]. In the ideal case, correlations between the ideal dimension score and its empirical equivalent should be very high (close to 1), while correlations between both dimensions should be low (close to 0) and non-significant.

---

[7] Note that error may occur due to similar causes for any of the scales, resulting in (measurement) error correlations. However, while errors may be related, they can still be different for each scale/sector. The relatedness of (measurement) error can also be specified in confirmatory factor models. However, models with much error (cor)relations are not very informative, and thus often not put to the test.

[8] Angle A of a sector (with the cooperation pole of the proximity dimension as the starting point) can be computed by the following formula: A=arctan(DS/CO), where DS and CO are factor loadings for the influence and proximity dimension, respectively. With the ideal factor loadings, one can compute ideal angular locations A(i) in a similar manner. Angular dislocation can be computed with the formula: A'=1-dev/180, where dev=A-A(i).

[9] Vector length=$\sqrt{(\text{influence}^2/\text{proximity}^2)}$, where influence=factor loading of sector on influence, proximity= factor loading of sector on proximity.

[10] Ideal dimension scores are computed as follows: Influence = (.92*DC) + (.38*CD) - (.38*CS) - (.92*SC) - (.92*SO) -(.38*OS) +(.38*OD) + (.92*DO); proximity = (.38*DC) + (.92*CD) + (.92*CS) + (.38*SC) - (.38*SO) - (.92*OS) -(.92*OD) - (.38*DO). In the empirical situation, .92 and .38 are replaced by values that resulted from factor analyses.

3. Previous research on validity and reliability of the QTI

As described earlier, many studies from several countries have reported on the reliability and validity of the QTI. A review on a selection of studies from the past 15 years shows that the reliability of the scales (sectors) of the QTI is very high (den Brok, 2001): Cronbach's alpha coefficients are roughly between .70 and .85 at the student level, and between .80 and .95 at the class level. Percentages of variance at the class level are also high, in most cases between 30 and 50. Confirmatory and exploratory factor analyses on the scale scores usually provide evidence for the existence of two, uncorrelated dimensions at the class level (den Brok, 2001; Wubbels & Levy, 1991). Additionally, researchers report that their correlation matrices seem to be ordered in terms of a circular structure (Evans, 1998; Henderson, 1995; Rawnsley, 1997; Rickards, 1998).

However, for data at the student level, researchers sometimes find three, or even more, factors or dimensions, and interpretation of factor loadings is not always straightforward (den Brok, 2001; van tartwijk, Brekelmans, Wubbels, Fisher, & Fraser, 1998). Several explanations have been provided for the existence of three or more factors (den Brok, 2001): *incompleteness* of the current model for interpersonal behavior (an additional dimension, for example 'degree of activity', is needed), *generality* of the current model of interpersonal behavior (a dimension should perhaps be divided into two subdimensions that represent the poles separately), introduction of *unintended (context) factors* in the measurement methods, and *methodological problems* (resulting in measurement error).

While previous studies have shown that the QTI is a high quality instrument and appears to be a valid representation of the Model of Interpersonal Teacher Behavior, most of the studies are subject to shortcomings:

- Methods were highly exploratory and descriptive in nature. If correlation matrices were inspected for circumplexity (to "test" assumption 3), this was done subjectively and without any statistical test. In many cases, exploratory factor analyses were used (to test assumptions 1 and 2). These kinds of analyses provided no (statistical) comparison with the ideal circumplex model, provided no overal model fit indicators to test whether data fitted the model specified and measurement error was not included in the models (or measurement error was underestimated). Moreover, researchers used principal components extraction and varimax rotation, which are not suitable for circumplex testing. In cases where confirmatory factor analyses were performed, only assumptions 1 and 2 were tested (e.g. factor loadings were not restricted but freely estimated).

- Methods ignored the nested structure of the data. Most of the studies analyzed student perception data, and analyzed this data at the individual (student) level. As a result, correlations between scales were probably overestimated, because the methods (confirmatory or exploratory factor analyses, correlational analyses) assumed random sampling. If respondents are sampled in clusters (as is the case in most educational studies), their answers will be more similar than in randomly sampled situations, because they share a similar history

and context (Hox, 1995; Muthén, 1994). Moreover, analyzing data on class level processes at the student level is questionable, since the model and its operationalization were specified and designed for the class level, rather than the individual level.

- Some studies aggregated student perception data to the class level. While these studies investigated data at the proper level, aggregation has serious drawbacks. It leads to loss of information and as a result lack of statistical significance in analyses (Hox, 1995).

- If data were analyzed at the student and class level simultaneously, the same structure was assumed at both levels, even though the MITB was formulated for the class level. Conceptually, at the individual level QTI-data represent *deviations of an individual student from the class mean* with respect to interpersonal teacher behavior. There may be various reasons for a student to differ from the class average, such as personal values and beliefs or even individual differences in treatment by the teacher (den Brok, 2001). Moreover, it has been shown that a two-dimensional circumplex model is not likely to support student perceptions at the individual level (den Brok, 2001). Other research shows that different structures may account for clustered data at different levels (Hox, 1995; Muthén, 1994).

- Due to the exploratory nature of factor analyses or inspection of correlation matrices, only some of the assumptions of the MITB have been tested. Since only one method of analysis was used in most cases, the studies also tested a single assumption at a time. Models found with exploratory methods were not compared to the theoretical ideal by means of computing of angles or vector lengths (e.g. Blackburn & Renwick, 1996; Wiggins, et al., 1989).

- Cross-cultural comparisons involved only two countries at a time. In these comparisons, factor loadings and correlation patterns were compared subjectively. Model fit indicators were not compared across countries.

The present study tries to overcome most of these limitations by comparing six countries (Australia, Netherlands, USA, Singapore, Brunei and Slovakia), and by using different methods of analysis to test the first five assumptions behind the MITB.

4. Research questions

Using data from six countries – Australia, USA, the Netherlands, Slovakia, Singapore and Brunei, the following research questions were investigated:

1) To what degree is the QTI capable in reliably and consistently measuring differences in interpersonal style between classes/teachers in six countries?

2) To what degree do students' perceptions, measured with the QTI, represent the MITB in each of the six countries?

researchers need to show equivalence of instruments. Instrument equivalence requires that instruments are equivalent in terms of conceptual structure (conceptual or functional equivalence), are equivalent in terms of operationalization (construct operationalization equivalence), are equivalent in terms of items (item equivalence) and are measured on the same degree of intensity, magnitude or measurement range (scalar equivalence). In this study, all of these requirements have been met, although establishing conceptual equivalence in itself is part of the research questions. Sample items for each of the sectors (scales) are given in Table 2.

Table 2
Typical Items for the Scales of the QTI

Scale (sector)	Typical item
DC – leadership	This teacher acts confidently.
CD – helpful/ friendly	This teacher is friendly.
CS – understanding	This teacher is patient.
SC – student responsibility/freedom	We can influence this teacher
SO – uncertain	This teacher is hesitant.
OS – dissatisfied	This teacher is suspicious.
OD – admonishing	This teacher gets angry quickly.
DO – strict	This teacher is strict.

5.2 Analysis procedure

The analysis procedure involved a number of steps. To answer the first research question, sector scores were used (the average of the 6 items that pertain to one sector or scale). Next, intra-class correlations, consistency estimates (Multilevel Lambda[11], Snijders & Bosker, 1999) and Cronbach's alpha (at the class level) were computed for the sector scores. Intra-class correlations were computed with the SPLIT2-software[12] (Hox, 1995). Cronbach's alpha and Multilevel Lambda were established with SPSS.

The second research question involved testing assumptions 1 to 5 on data from each of the six countries. The testing of these assumptions was done with different kinds of software, each of which analyzed intercorrelations between the sectors of the QTI. Unfortunately, some software packages, RANDALL and CIRCUM, cannot handle multilevel data. Therefore, class-level correlation matrices were computed that served as input for these programs. These matrices were so-called *uncontaminated class-level correlation (or covariance) matrices*. These matrices are different from matrices based on aggregated data in that they uniquely contain class level variance, rather than being a combination of individual and class variance (as is the case for aggregation). Uncontaminated class level correlation matrices take the nested structure of the data into account, meaning that in their computation no information is lost (which is the case for aggregation). To arrive at these uncontaminated class level matrices, we first used SPLIT2 to compute a class level and individual level correlation matrix for each country data set. The resulting class level correlation matrix, however, was still contaminated

---

[11] Lambda=N_j*ICC/(1+(N_j-1)*ICC), where ICC=intra class correlation and N_j=average group size.

5. Method

5.1 Sample and instruments

To answer the research questions, QTI data were obtained from researchers that conducted their studies in each of the countries of interest, and were then re-analyzed to meet the purposes of the present study. To enhance comparison between countries, researchers were asked to provide only data on secondary Science (Physics and Chemistry) teachers. Data were used from the Netherlands (919 students rating 65 teachers), USA (800 students rating 40 teachers), Australia (726 students rating 35 teachers), Singapore (1,713 students rating 50 teachers), Slovakia (490 students rating 18 teachers) and Brunei (644 students rating 35 teachers).

Table 1 presents some characteristics for the samples in each of the countries. As can be seen, samples included considerably smaller number of schools in Australia, the USA, Slovakia and Singapore than in the other countries. Moreover, average class size varied from country to country, and ranged between 18 (Brunei) and 34 (Singapore) students. In all countries, the majority of the classes involved grades 8 to 10. Average teacher experience was high in all countries, except for the U.S. Some of the differences found represented sampling procedures used. The Dutch sample was taken from a large-scale study involving many other research instruments. As a consequence, only half of the students in a class completed the QTI. In all countries, *convenience* sampling was used, except for the Netherlands, were teachers were *randomly* sampled. In the U.S. this convenience sample comprised a selection of multicultural schools and beginning teachers, since data were gathered as part of a professional development programme for teachers. In Slovakia, the sample also contained Mathematics teachers.

Students in each country completed the QTI in their respective languages. In Australia, Singapore and Brunei, a 48-item version of the QTI was used. The QTI in the USA and Slovakia consisted of 64 items, while the Dutch (original) version consisted of 77 items. In each country, the items referred to eight scales, representing the eight sectors of the MITB. For comparative purposes, the same 48 items as present in the Australian, Singapore and Brunei versions were selected from the Dutch, American and Slovakian data samples. According to Wubbels (1985, following Hui & Triandis, 1985), before cross-national equivalence of validity and measurement can be established,

Table 1
Characteristics of the Country Samples

	N-students	N-classes	N-schools	Average group size	Grades	Teacher experience
Australia	726	35	12	20.7	8-10	High
United States	800	40	7	20.0	7-11	Medium
Netherlands	919	65	45	14.1	9	High
Slovakia	490	18	12	27.2	9-10	High
Singapore	1713	50	9	34.3	8-10	High
Brunei	644	35	23	18.4	8-10	High

The fifth and last assumption[17] was tested by formulating an ideal circumplex model in Mplus. In this model, two factors were specified, with fixed factor loadings according to Figure 1, and the correlation between the two factors was set to zero. Model fit was assessed by looking at the model fit indicators.

Finally, it was determined to what degree empirical locations of sectors deviated from their theoretical (e.g. ideal) position. Empirical factor loadings were taken from the exploratory factor models, used for testing assumption 1. Then, angular dislocation, relative angle distance and vector length of sectors were computed (Blackburn & Renwick, 1996). Finally, SPSS was used to compute correlations between empirical and ideal dimension scores. To achieve this, for each teacher dimension scores were computed with the empirical factor loadings and with the ideal factor loadings.

6. Results

6.1 Reliability, consistency and variance at class level

Reliability of the sector scores at the class level was above .80 in most countries (see Table 3). In most countries, reliability was lowest for the student responsibility/freedom sector (SC) and strict sector (DO). On average, reliability was highest for Australia and Singapore. Intra-class correlations of sectors generally were above .20, but varied from sector to sector and from country to country: the largest differences between classes existed in the Dutch sample (average intra-class correlation of .41), while the smallest differences existed for the USA, Australia and Brunei (average intra-class correlations of .24, .25 and .24, respectively). This meant that the QTI was better able to detect differences between teachers in the Netherlands and Slovakia, than in the USA, Australia and Brunei. Constency across classes (Multilevel Lambda) was high (above .80) for all sectors in all countries.

---

[17] The sixth assumption, assuming equal error variance across sectors, was not tested.

14

(since it still was a combination of student and class level variance; see Hox, 1995). Therefore, these matrices were entered into LISREL and a *saturated model* (see Hox, 1995) was specified with the multiple-group option[13]. The output of the LISREL set-up for these models then provided uncontaminated correlation estimates, that could be used for further analyses. The uncontaminated class level correlation matrices for each country can be found in Appendix 1.

To test the first assumption, exploratory factor analyses (SPSS) were performed on the uncontaminated class-level correlation matrices, using Maximul Likelihood extraction (no rotation). In the analyses, only factors with an eigenvalue larger than one were selected. The optimal number of factors was determined by looking at the decline in eigenvalue (scree-plot). The first assumption was also tested by means of confirmatory factor analyes (Mplus), specifying two-factor models (in a multilevel set-up) with free factor loadings and correlation between the two factors[14]. Model fit was determined by looking at the Chi-squared/df ratio (should be non-significant), Root Mean Squared Error of Aproximation (RMSEA, should be smaller than .05), Comparative Fit Index (CFI) and Tucker Lewis Index (TLI)[15].

The second assumption was tested by means of confirmatory factor analyses with Mplus. Models were the same as for assumption 1 (two factors with freely estimated factor loadings), but the correlation between the two factors was set to zero. Model fit was determined in the same manner as was done for assumption 1.

The third assumption was tested by entering the uncontaminated class-level correlation matrices of Appendix 1 into RANDALL. This resulted in Correlation Indices (CI) for each matrix, as well as a probability estimate. Next, the number of assumptions met and violated were reported. Also, the assumption was tested by formulating a non-equally spaced circumplex model (non-equal communalities) in CIRCUM. Model fit was assessed by looking at the Chi-squared/df ratio, RMSEA, CFI and TLI[16].

The fourth assumption was tested by formulating an equally-spaced circumplex model (non-equal communalities) in CIRCUM. Again, model fit was assessed by looking at the model fit indicators.

---

[13] In LISREL a multilevel model can be specified using the multiple group option. The model specifies the student level part in the first group and the class or teacher level part in the second group. Since the class level correlation matrix of SPLIT2 (or other software that can be used to decompose the data according to levels) still contains individual as well as class level variance, the student level part is also specified in the second group. This is done by constraining the student level part of the model – in this situation a saturated model – to be equal for both groups. The uncontaminated class level correlation matrix can then be found as the standardized psi matrix in the output.

[14] For estimation purposes, a few estimates in the model need to be fixed, since if this is not done, models will be over-identified. In our case, the factor loadings between the first factor and DC as well as the factor loading between the second factor and CS are set to 1. Also, the factor loading between the first factor and SO is set to -1.

[15] RMSEA, CFI and TLI have the advantage that they are not related to sample size. RMSEA is a measure that takes the amount of residual variance into account, while CFI and TLI are indices that compare the fit of the model to no model at all (null model). CFI and TLI values should be above .95 for adequate fit.

[16] TLI and CFI are not provided by CIRCUM, but can be calculated by hand from available model fit indicators.

13

can be seen, this hardly changed CFI, TLI or RMSEA values, indicating that it is very probable that the two dimensions are independent. In the Australian data set, chi-squared even became smaller if the correlation was set to zero, indicating better model fit. In the other countries, chi-squared only increased by small amounts.

Table 4
Fit indicators of Models Testing Circumplex Assumptions

Country	Model	χ^2	df	p-value	RMSEA	CFI	TLI
Australia	Exploratory model (ass. 1)	79.947	14	<.000	.081	.97	.88
	Independent dimensions model (ass. 2)	75.589	13	<.000	.081	.97	.88

Slovakia	Exploratory model (ass. 1)	26.199	13	.0160	.046	.99	.97
	Independent dimensions model (ass. 2)	27.776	14	.0152	.045	.99	.97
	Circular order model (ass. 3)	20.90	10	.0230	.253	.92	.77
	Equally spaced circumplex model (ass. 4)	57.36	17	<.000	.374	.70	.50
	Ideal circumplex model (ass. 5)	109.200	26	<.000	.081	.95	.90
Singapore	Exploratory model (ass. 1)	79.099	13	<.000	.064	.98	.92
	Independent dimensions model (ass. 2)	83.052	14	<.000	.063	.98	.92
	Circular order model (ass. 3)	43.32	10	<.000	.261	.91	.75
	Equally spaced circumplex model (ass. 4)	128.48	17	<.000	.366	.70	.51
	Ideal circumplex model (ass. 5)	182.892	26	<.000	.070	.95	.90
Brunei	Exploratory model (ass. 1)	33.515	13	.0014	.050	.99	.95
	Independent dimensions model (ass. 2)	37.550	13	<.000	.054	.99	.95
	Circular order model (ass. 3)	30.94	10	<.000	.248	.92	.78
	Equally spaced circumplex model (ass. 4)	87.71	17	<.000	.350	.74	.56
	Ideal circumplex model (ass. 5)	132.437	26	<.000	.080	.94	.88

Note: Since CIRCUM cannot handle multilevel data, Chi-squared, RMSEA, TLI and CFI values cannot be compared between models for assumptions 3 or 4 and models for the other assumptions (tested with Mplus).

According to the third assumption, sectors should display ordering in a circular structure. Analyses testing this assumption on the uncontaminated class-level correlation matrices (RANDALL) showed relatively high correspondence indices (CI) for all countries. In the Australian data, CI was .84 (p=.0008), with 264 out of 288 predictions met and 24 not met. For the USA, a CI of .78 (p=.0004) was found, with 255 out of 288 predictions met; for the Netherlands CI was .83 (p=.0004) with 262 predictions met; for Slovakia CI was .65 (p=.0012) with 238 predictions met; for Singapore CI was .67 (p=.0008) with 240 predictions met; and for Brunei CI was .70 (p=.0004) with 244 predictions met. These outcomes indicated that the sector intercorrelations corresponded with a circular ordering best

6.2 Testing circumplex assumptions

According to the first assumption, the eight scales of the questionnaire should be represented by two factors or dimensions. Exploratory factor analyses (maximum likelihood) on the uncontaminated class-level correlation matrices showed that this was the case for all six countries. Moreover, the two factors explained considerable amounts of variance: 78.8 percent in the Australian data set, 81.5 percent in the American data, 79.0 percent for the Dutch data, 79.7 percent for the Slovakian data, 73.8 percent for the Singapore data and 76.2 percent for the Brunei data. Also, the second dimension explained more than 10 percent in all data sets. This indicated that student perception data of the QTI could be structured in terms of two interpersonal dimensions in all countries.

Analyses testing freely estimated two-factor models that allow for correlation between the factors (Mplus) also indicated close fit to the data (see Table 4). CFI values were above .95 in all data sets, while TLI values were above .95 for the USA, Slovakia and Brunei and were close to .90 for the other countries. RMSEA was close to .05 in most cases, being the highest for Australia (.081) and the Netherlands (.067). Chi-squared values were significant in all cases, which is mainly due to the relative large sample sizes for the individual level part of the data. While fit was far from perfect, it seemed that two dimensions structured the perceptions of interpersonal behavior as measured with the QTI in all countries.

The second assumption states that the two interpersonal dimensions should be uncorrelated. Table 4 lists the results of confirmatory factor analyses where the correlation has been set to zero. As

15

or Australia and the Netherlands and worst for Slovakia and Singapore. Nevertheless, CI values were sufficiently high to support a circular ordering in all countries.

A more stringent test of circular ordering of the scales is provided by confirmatory analyses specifying a non-equally spaced circumplex (non-equal communalities). According to Table 4, there was no support for a circular order model in any of the countries, since Chi-squared values were significant and RMSEA values were unacceptably high. One possible reason for this may be that some of the scales almost take similar positions on the interpersonal circle, such as CD and CS, or OS and OD. As a result, the sectors displayed an eliptical structure, rather than a circular structure.

According to the fourth assumption, scales should be equally distributed over the interpersonal circle. Models testing the uncontaminated class-level correlation matrices for this assumption showed poor model fit, with significant Chi-squared values and very high RMSEA values (see Table 4). Thus, it seemed unlikely that sectors were equally distanced in any of the countries.

Finally, the fifth assumption even specified exact locations of the sectors on the interpersonal circle. Fit indicators of models testing this assumption within a multilevel set-up (Mplus) indicated that this assumption could not be supported. This was not surprising, given the outcomes with respect to assumptions 3 and 4. Chi-squared values were significant, RMSEA values were higher than acceptable, while TLI values were lower than acceptable. Nevertheless, CFI values were acceptable for some countries (USA, Slovakia and Singapore), and nearly acceptable in the other countries.

In conclusion, it seemed that the QTI represented the MITB reasonably well with two independent dimensions structured sector scores, and could be ordered in a circular structure. However, scales were not equally distributed over the circle, nor did they occupy similar distances to the circle center, nor did they take the exact positions hypothesized by the model.

6.3 Difference between empirical and theoretical model

The above results raise the question to what degree the empirical model behind the data is different from the theoretical ideal. To investigate this, we have used the factor loadings found for models that tested the first assumption. These factor loadings are graphically displayed in Figures 2 to 7, and in numerical form in Table 5. In Table 5, the absolute average difference between empirical and theoretical factor loadings per dimension is also given. As can be seen in Table 5, differences between empirical and theoretical factor loadings are largest for Slovakia for the influence dimension, while they are largest for Singapore for the proximity dimension. They are smallest for Singapore for the influence dimension and smallest for the Netherlands for the proximity dimension.

Figure 2
Australia - factor loadings

Figure 3
USA - factor loadings

Figure 4
Netherlands - factor loadings.
Figure 5
Slovakia - factor loadings
Figure 6
Singapore - factor loadings

Figure 7
Brunei - factor loadings

Figures 2 to 7 confirmed that in most countries an elliptic, rather than circular, structure could be found, and that some of the scales hardly occupied different positions in the interpersonal plane.
Table 5

Empirical factor loadings in six countries.

Scale	Australia DS	CO	United States DS	CO	Netherlands DS	CO	Slovakia DS	CO	Singapore DS	CO	Brunei DS	CO
DC				1.								1.
CD		1.		1.						1.		
CS		1.								1.		
SC										1.		
SO		-1.				-1.						-1.
OS				-1.						-1.		-1.
OD				-1.						-1.		-1.
DO										-1.		-0.
Diff												

Note: Diff = absolute average difference between theoretical and empirical factor loadings for the dimension.

The next step consisted of establishing the exact difference between empirical and theoretical positions of the sectors. Therefore, angular dislocation was computed (see footnote #8) in terms of degrees (Table 6) and in terms of relative angle distance (Table 7).

Table 6

Angular dislocation in degrees.

	DC	CD	CS	SC	SO	OS	OD	DO
Australia	-17.3	-19.6	-31.4	-19.4	27.0	-16.4	14.3	27.5
United States	-21.7	-9.4	-30.8	9.9	0.1	-8.6	22.4	28.6
Netherlands	-4.5	-0.1	-37.1	31.8	31.1	-17.5	13.2	32.3
Slovakia	-23.4	-15.9	-24.9	64.6	-19.9	-45.2	17.5	28.6
Singapore	5.7	7.1	31.6	-33.0	-25.4	13.5	-14.3	-40.5
Brunei	10.5	-2.8	-20.7	-30.6	-33.1	20.2	-7.6	-33.0

All sectors shifted from their 'theoretical' position to some degree. This was particularly true for the understanding (CS), student responsibility/freedom (SC), and strict (DO) sectors in most countries. The understanding (CS) sector had moved more than 30 degrees clockwise in the Dutch, Australian and American samples, but in a counter-clockwise direction in the Singapore sample. The student responsibility/freedom (SC) sector had moved more than 30 degrees counter-clockwise in the Dutch and Slovak samples and more than 30 degrees in clockwise direction in the Singapore and Brunei samples. Thus, these two sectors were relatively closely positioned in the Dutch sample, but relatively distant in the Singapore sample. The strict (DO) sector had moved considerably counter-clockwise in the Dutch sample, but clockwise in the Singapore and Brunei samples. Thus, in the Dutch sample strictness incorporated less *influence* than theoretically hypothesized and more *proximity*, while the opposite was true for Brunei and Singapore.

Table 7

Relative angular dislocation.

	DC	CD	CS	SC	SO	OS	OD	DO	Mean dislocation
Australia	.90	.89	.83	.89	.85	.91	.92	.85	.88
United States	.88	.95	.83	.95	.99	.95	.88	.84	.91
Netherlands	.98	1.00	.79	.82	.83	.90	.93	.82	.88
Slovakia	.87	.91	.86	.64	.89	.75	.90	.84	.83
Singapore	.97	.96	.82	.82	.86	.93	.92	.77	.88
Brunei	.94	.98	.88	.83	.82	.89	.96	.82	.89
Overall	.92	.95	.84	.83	.87	.89	.92	.82	

Table 7 is another means of displaying the "shifts" in position of sectors. As can be seen, the strict sector (DO) was most dislocated outcomes are similar to those of Table 5. As can be seen, the strict sector (DO) was most dislocated (.82), followed by the student responsibility/freedom (SC) sector (.83) and understanding (CS) sector (.84). The sectors least dislocated were the helpful/friendly (CD) sector (.95), leadership (DC) sector (.92) and admonishing (OD) sector (.92). When comparing the mean or average dislocation per country, it could be seen that for the American data set sectors were least dislocated (.91), while they were most dislocated for the Slovakian data set (.83). However, differences in mean dislocation between countries were small.

Apart from angular dislocation, dislocation was also determined with respect to distance from the circle center (see footnote #9 for computation). Ideally, all sectors should have equal distance to the circle center. Vector length is presented in Table 8.

Table 8

Vector length (distance to circle centre) of sectors of QTI.

	DC	CD	CS	SC	SO	OS	OD	DO	Mean	Variance
Australia	.94	1.42	1.11	1.05	1.00	1.14	1.46	.95	1.14	.167
United States	1.02	1.32	1.02	.91	.92	.92	.92	.72	.97	.157
Netherlands	1.02	.97	.92	.48	.93	.81	.81	.66	.83	.171
Slovakia	1.32	1.22	.92	1.22	1.22	1.22	1.62	1.52	1.29	.200
Singapore	.92	1.22	1.26	1.66	1.12	1.21	1.76	1.52	1.35	.258
Brunei	1.06	1.22	.92	.62	.62	1.14	1.42	1.02	1.11	.227

Table 8 displays a number of interesting patterns. First, vector length varied per sector from country to country, with the largest differences found for the student responsibility/freedom (SC) sector (ranging between .48 for the Netherlands and 1.66 for Singapore), the admonishing (OD) sector (ranging between .81 for the Netherlands and 1.76 for Singapore) and strict (DO) sector (ranging between .66 for the Netherlands and 1.52 for Slovakia). Second, according to the ideal (theoretical) circumplex model, variance in vector length should be minimal (zero). As can be seen, considerable variance in vector length was found within each country, with the USA displaying the least variance and Singapore the most variance. Also, it can be seen that the average distance of scales to the circle center was smallest for the Netherlands (.83) and largest for Singapore (1.35).

Finally, we computed correlations between empirical and theoretical dimension scores (see footnote #10). These correlations are given in Table 9 and can be seen in all countries a close

more precise estimates of effects and correlational structures of interest. Sometimes, using such techniques can also show interesting interactions between variables, and may alter previous findings completely (e.g. den Brok, Levy, Wubbels & Brekelmans, in press). Research on validity of learning environment instruments may particularly benefit from the use of Structural Equation Modelling (SEM) techniques, such as used in this study. Structural Equation Modelling allows researchers to test specific hypotheses or assumptions behind their data, provides indices for the fit of a model to a particular data set and provides researchers with the means to take measurement error into account. One could, for example, apply these techniques to test whether the learning environment dimensions of Moos (1979) structure scale scores of instruments such as the *Learning Environment Inventory* (LEI), *Classroom Environment Scale* (CES) or *What Is Happening In this Class* (WIHIC). Such investigations would lead to increased insight into the structuring of student perceptions and the internal validity of such instruments.

While the study compensated for some earlier limitations, the study itself was also subject to limitations. First, sampling procedures and characteristics varied between countries. This may have led to between-country differences in validity. Also, sample sizes varied from country to country and were quite small for some countries. Research has shown that in order to achieve stable results, more than 50 teachers/classes are needed (Hox & Maas, 2001). Also, while a selection of items was used for three countries to enhance comparison, and these selections still appeared to display reasonable validity, it may well be that the 'complete' instruments would show different results, and even better validity. Thus, this study to some degree ignored differences in the development between countries.

Then, validity testing concentrated on the class-level, while the individual level of the data was not subjected to validity testing. Earlier research showed that different structures may apply to these levels. Testing structures at these levels between countries would also have been interesting. Finally, while the structure behind perceptions was tested, it was not tested whether differences in interpersonal behavior occurred between countries, either in terms of scales or dimensions. Other aspects of validity, such as predictive validity, were not compared between countries. Neither did the study investigate whether differences in interpersonal styles existed between countries. Researchers may use the outcomes of the present study to make such comparisons in future research with some reassurance that the QTI displays similar structures in different countries.

Finally, the QTI appears to be cross-country comparable in terms of validity. This opens up opportunities to start international studies on teaching practice, joint research or professional development projects between countries, or using the instruments in multicultural and international schools settings. It may help researchers, supervisors, school management and teachers to develop a common language to discuss their practice.

esemblance was found between empirical and theoretical dimension scores. For *proximity* correlations ranged between .956 for the Brunei sample to .998 for the American, Dutch and Slovak samples. For *influence* correlations ranged between .899 for the Dutch sample to .993 for the Australian sample. These high correlations show that, despite irregularities found with the MITB in each of the countries (as described in testing assumptions 1 to 5), the QTI was capable of closely reproducing theoretically expected dimension scores in all countries.

Table 9
Correlations between ideal and empirical dimension scores of QTI.

	Influence	Proximity
Australia	.993	.993
United States	.922	.997
Netherlands	.899	.998
Slovakia	.973	.998
Singapore	.972	.977
Brunei	.967	.956

Summarizing the above findings, it can be concluded that irregularities from the ideal circumplex mainly related to dislocation in the understanding, student responsibility/freedom and strict sectors. While country-to-country differences were found, the QTI was capable of closely reproducing ideal dimension scores in all countries.

7. Discussion

In this article, the validity of the QTI was compared for samples of secondary science teachers in six countries. The QTI is supposed to be an adequate operationalization of the MITB which can be regarded as a manifestation of a circumplex model. Validity was investigated in terms of testing 5 assumptions that lay behind circumplex models.

In general, the outcomes of the study support the existence of two dimensions (assumption 1), which are uncorrelated (assumption 2). Some support was found for a circular ordering of the sectors (assumption 3), but no support was found for equal distancing of sectors across the circle (assumption 4) and specific hypothesized locations of the sectors on the circle (assumption 5). Thus, a two-dimensional circular structure may lay behind the QTI, but empirical positions of the sectors on this circle deviate from their theoretically ideal positions. These deviations particularly occurred for the strict (DO), understanding (CS) and student responsibility/freedom (SC) sectors.

Some of the outcomes of the study are particularly interesting. First, country-to-country differences were found in the positions of the sectors on the interpersonal circle. For example, student responsibility/freedom and understanding occupied nearly similar positions on the circle in the Netherlands, while a large distance between them was found in Singapore. The understanding sector contained less influence than expected in Australia, the Netherlands and the USA while it included more influence than was expected in Singapore; the student responsibility/freedom sector had more

influence and proximity than expected in the Netherlands and Slovakia, but less influence and proximity than expected in Singapore and Brunei. Also, strictness seemed to incorporate less influence in the Netherlands than hypothesized, while it incorporated more influence than hypothesized in Singapore and Brunei. These between-country differences might reflect different meanings or connotations attached to the sectors of interest. However, they might also reflect differences in focus: in some countries strictness or student responsibility may be observed from different cues than in other countries, or cues may be valued differently in terms of importance, even if (some) equivalence in meaning exists. Finally, the differences might be caused by the QTI development process (which was different from country to country), sampling procedure or characteristics (which also differed from country to country). Further in-depth research on between-country differences in sector positions is needed. This research should include interviews with students and/or teachers regarding the meanings attached to certain concepts, particularly strictness, understanding and student responsibility. Interesting questions would be whether Dutch students regard understanding and student responsibility as similar concepts and why Singaporean students regard them as (completely) different. Also, it would be interesting to see if students from different countries use different cues to form their perceptions (observe different elements). For example, is strictness inferred from the same verbal and non-verbal behaviors by Dutch and Singaporean or Brunei students? Also, it could be investigated how important these differences really are. In this study, for example, it was found that while sectors occupied different positions than hypothesized and between-country differences were found in this respect, correlations between empirical and theoretical dimension scores were extremely high in all countries and hardly varied between countries. Also, earlier research has shown that the interpersonal dimensions and sectors display similar relationships with student outcomes in different countries, both in terms of directions and magnitude (e.g. Brekelmans, Wubbels, & den Brok, 2002; Fisher, et al., 1996).

From a research point of view, the fact that some sectors display huge amounts of overlap may lead to the conclusion that some sectors can be omitted from the model. Another conclusion may be that different items should be added to the list that may alter the position of the sector(s) on the circle. Despite such possible alterations, the instrument in its current form may still be interesting and necessary from a feedback or training point of view.

Another interesting conclusion that may be drawn from the outcomes of this study is the fact that short versions of the QTI from the USA and Netherlands are almost equally valid as their longer equivalents. This may lead to considerably shortening of the instruments for use in future research or professional development activities.

The methods used in this study may be of particular importance for the field of learning environments research. First of all, it has been concluded that research in this domain hardly uses multilevel analyses techniques, while the data in most cases are hierarchical in nature (e.g. Fraser, 1998). Therefore, using techniques that adjust for multi-stage sampling (non-random data) may lead to
